SELF-ASSESSMENT QUESTIONS

1. Which of the following is a maladaptive pain state?

A. Acute post-op pain

B. Ankle sprain

C. Fibromyalgia

D. Pain associated with an infection

2. In which phase of nociception is a noxious stimulus converted into an action potential?

A. Conduction

B. Transmission

C. Modulation

D. Perception

3. Which of the following is an excitatory neurotransmitter involved in pain transmission?

A. B-endorphin

B. Y-aminobutyric acid (GABA)

C. Glutamate

D. Norepinephrine

4. What mechanism is principally involved in the maintenance of maladaptive pain states?

A. Altered pain processing in the CNS

B. Upregulation of sodium channels in the PNS

C. Excessive prostaglandin synthesis

D. Overproduction of endorphin neuropeptides

5. Which of the following is believed to augment the descending inhibitory pathway to produce analgesia?

A. Cognitive behavioral therapy

B. Massage

C. Mindfulness-based stress reduction

D. Transcutaneous electrical nerve stimulation (TENS)

6. The dose of breakthrough pain medication (exception rapid-acting fentanyl) is generally calculated as:

A. 5% of the total daily dose of opioids

B. 10% to 15% of the total daily dose of opioids

C. 25% to 50% of the total daily dose of opioids

D. 50% to 75% of the total daily dose of opioids

7. Which of the following options is an optimal nonopioid medication for a person with significant musculoskeletal pain and comorbid depression?

A. Amitriptyline

B. Duloxetine

C. Lamotrigine

D. Milnacipran

8. When initiating oral transmucosal fentanyl citrate the most appropriate starting dose is?

A. The lowest available dosage form

B. One-half of the 24-hour morphine equivalent intake

C. Equal to the 24-hour morphine equivalent intake

D. Twice the 24-hour morphine equivalent intake

9. Which of the following adverse effects is considered a transient side effect of opioids?

A. Hypogonadism

B. Somnolence

C. Constipation

D. Pruritus

10. You have a patient who is treated with erythromycin (potent CYP 3A4 inhibitor) for diabetic gastroparesis, having painful diabetic peripheral neuropathy and is on numerous adjuvant analgesics with no effect. The decision has been made to place the patient on long-term opioid therapy. Which of the following opioids would you NOT recommend due to potential drug–drug interactions?

A. Morphine

B. Hydromorphone

C. Oxycodone

D. Fentanyl

11. Which of the following best describes the mechanism of action of tapentadol?

A. Mu-opioid agonist

B. Mu-opioid agonist plus serotonin > norepinephrine reuptake inhibition

C. Mu-opioid agonist plus norepinephrine > serotonin reuptake inhibition

D. None of the above

12. Which of the following two analgesics are actually prodrugs requiring metabolism to their active metabolite for analgesia?

A. Hydrocodone and hydromorphone

B. Codeine and tramadol

C. Tramadol and tapentadol

D. Morphine and codeine

13. When starting methadone, titration (increase) in dosing should NOT occur more frequently than:

A. Once a day

B. Twice a week

C. Weekly

D. Monthly

14. Which of the following would be considered components of a risk mitigation strategy for monitoring unhealthy use with opioid prescriptions?

A. Prescription Drug Monitoring Programs

B. Urine Drug Screening

C. Patient-Provider Agreements

D. All of the above

15. When converting from one opioid to another using equianalgesic dosing tables, the target drug dose should be decreased by ___________ to account for lack of cross-tolerance between opioids.

A. 10%

B. 25%

C. 75%

D. 90%

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Fibromyalgia is considered a maladaptive pain state, in that it does not provide any protective function. Acute post-op pain, ankle sprain, and pain associated with infection all alert the brain that tissue damage has occurred and prompts the symptom of pain in order to protect injured tissue from further damage/insult (see "Pathophysiology" section).

2. **A.** Noxious stimuli are converted to action potentials during the *conduction* phase of nociception. Transmission refers to the spread of the action potential through the neuron. Modulation is the central nervous system's response to the nociceptive signal and serve as the "brakes" to keep pain from growing more severe than is physiologically necessary. Perception involves numerous pathways in the brain in which the body *localizes* the pain origin and mounts an *emotional* response to the pain, depending on severity (see "Pathophysiology" section).

3. **C.** In pain transmission, B-endorphins, gamma-aminobutyric acid, and norepinephrine all play either a direct or indirect inhibition role to slow primary and secondary neuron depolarization. Glutamate is the primary excitatory neurotransmitter found in vesicles in the pre-synapse (see "Pathophysiology" section).

4. **A.** While upregulation of sodium channels in the peripheral nervous system may certainly contribute to heightened pain response, altered processing in the central nervous system is primarily involved in the development of maladaptive pain states. Prostaglandins and endorphin neuropeptides will typically have an inhibitory role in nociception and pain processing (see "Pathophysiology" section).

5. **D.** Transcutaneous electrical nerve stimulation (TENS) is thought to assist the nervous system in the *modulation* of pain via the descending inhibitory pain pathway. This may be due to changes in activated neurons. Cognitive behavioral therapy, while helpful in the treatment of acute and chronic pain, focuses on coping skills, as does mindfulness-based stress reduction. Massage may impact the ascending pain pathway (see Table 79-3).

6. **B.** While no clear guidelines exist to help guide breakthrough pain dosing of opioids, providing enough immediate release opioid for breakthrough pain is essential as the higher the dose received over a 24-hour period, the higher the dose of immediate release opioid that will be required. In cancer pain models, 10% to 15% has generally be proven effective as a ratio of the total daily opioid dose (see Table 79-4).

7. **B.** Duloxetine is the only nonopioid antidepressant analgesic that possesses an FDA approval for the treatment of chronic musculoskeletal pain. The other choices do not possess sufficient evidence to support their use in such pain states (see Table 79-8).

8. **A.** Breakthrough pain dosing opioid immediate release opioids is typically derived from a percentage of total daily opioid dose. This is not true for transmucosal immediate release fentanyl products, given their unpredictably transmucosal absorption. Therefore, product prescribing information recommends starting at the lowest available dose of transmucosal fentanyl and titrating to affect (see Table 79-12).

9. **B.** Opioids have numerous unique adverse effects. Patients may develop tolerance to some. Nausea and somnolence typically subside after 2 to 3 days of continued dosing. Hypogonadism, constipation, and pruritus typically continue despite ongoing therapy (see Table 79-14).

10. **D.** Fentanyl is metabolized to norfentanyl via CYP 3A4. Morphine and hydromorphone undergo glucuronidation to morphine-3-glucuronide, morphine-6-glucuronide and hydromorphone-3-glucuronide, hydromorphone-6-glucuronide, respectively. Oxycodone largely undergoes metabolism via CYP 2D6 to its active metabolite, oxymorphone. Oxycodone does undergo metabolism in part via CYP 3A4; however, this is to an inactive metabolite, noroxycodone. (See Table 79-11.)

11. **C.** Tapentadol is a weak mu-opioid agonist as well as norepinephrine reuptake inhibitor. While it does possess some mild serotonin reuptake inhibition, this is of a much lesser extent when compared to tramadol or other serotonergic active drugs (see "Central-Acting Opioids" section).

12. **B.** The Clinical Pharmacogenomics Implementation Guidelines recommend CYP 2D6 genotyping when considering initiation of codeine or tramadol as both of these agents must be metabolized via CYP 2D6 to their active metabolites for analgesic activity. Other answers include opioids that have analgesic activity without conversion to other more active metabolites (see "Personalized Pharmacotherapy" section).

13. **C.** Methadone's extended and unpredictable half-life results in maximum analgesic efficacy (and risk of adverse effects) once it reaches steady state, which typically occurs in 5 to 7 days. Titration earlier than weekly may result in dose stacking and risk overdose. Monthly titration would be too long if titrating to effect for a patient with uncontrolled pain (see "Methadone and Congeners" section).

14. **D.** Any opportunity to identify aberrant drug-taking behaviors or signs/symptoms of opioid use disorder should be utilized when managing opioid therapy. Additionally, pharmacists have a corresponding responsibility to ensure safe use and prevent diversion of these substances. (see “Tolerance, Hyperalgesia, Physical Dependence, and Opioid Use Disorder” section).

15. **B.** While most of the opioids used clinically are mu-opioid agonists, several subtypes of mu-opioid receptor exist, resulting in potential differences in the cross-tolerance to different opioids. To ensure patient safety, target opioid dose should be empirically reduced by 25% to 50% to account for this lack of cross-tolerance and to prevent possible oversedation or overdose (see Table 79-4).

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 80: Headache Disorders

Kimberly B. Tallian; Natalie T. Heinrich

KEY CONCEPTS

KEY CONCEPTS

① Acute migraine therapies should provide consistent, rapid relief and enable the individual to resume normal activities at home, school, or work.

② The selection of initial treatment is based on headache-related disability, symptom severity, and preference for the individual with migraine.

③ Strict adherence to maximum daily and weekly doses of anti-migraine medication is essential.

④ Preventive therapy should be considered for recurring migraine attacks that produce significant disability; frequent attacks requiring symptomatic medication more than twice per week; symptomatic therapies that are ineffective, contraindicated, or produce serious adverse effects; and uncommon migraine variants that cause profound disruption and/or risk of neurologic injury.

⑤ The selection of an agent for headache prophylaxis should be based on individual response, tolerability, convenience of the medication formulation, and coexisting conditions.

⑥ Each prophylactic medication should be given an adequate therapeutic trial (usually 6 months) to judge its maximal efficacy.

⑦ A general wellness program that considers headache triggers should be included in the management plan.

⑧ After an effective abortive agent and dose have been identified, subsequent treatments should begin with that same regimen.

BEYOND THE BOOK

BEYOND THE BOOK

Read the article by Vandenbussche N, Laterza D, Lisicki M, et al.[23]

Review other existing literature related to whether medication-overuse headache is a distinct entity. Summarize two key points on both the pro and con sides of the issue. Be prepared to discuss or debate in class. (Note to instructors: It would be a good opportunity to assign teams and have an in-class discussion or formal debate.)

INTRODUCTION

Headache is among the top five principal reasons adults 18 to 44 years of age visit US emergency departments and are one of the most common complaints encountered by healthcare practitioners.[1] They can be symptomatic of a distinct pathologic process or can occur without an underlying cause. In 2018, the International Headache Society (IHS) updated its classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain.[2] The IHS classification provides more precise definitions and standardized nomenclature for both the primary (migraine, tension-type, and cluster headache) and secondary (symptomatic of organic disease) headache disorders. These criteria are designed to facilitate headache diagnosis in clinical practice, as well as being used for research. This chapter focuses on the management of primary headache disorders.

Most recurrent headaches result from a benign chronic primary headache disorder, with the most common being tension-type and migraine headache.[3] The peak prevalence for these headaches occurs during the most productive years of life (18-54 years of age).[4] Despite this and their associated disability, most headache sufferers do not obtain appropriate medical care for their headaches.[4,5] While most are benign, some headaches are symptomatic of a serious underlying medical condition, such as an infection, cerebral hemorrhage, or brain mass lesion. Therefore, a thorough evaluation of the headache history is essential to establish an accurate headache diagnosis and identify individuals who can benefit from these specific therapeutic options. In addition, advances in the field's understanding of the diagnosis and pathophysiologic mechanisms of the primary headache disorders, particularly migraine, have led to the development of medications that provide rapid relief from moderate to severe attacks.

MIGRAINE HEADACHE

Epidemiology

Approximately 20.7% of females and 9.7% of males in the United States experience one or more migraine headaches per year. While the prevalence of migraine varies by age and sex, the epidemiologic profile has remained stable over the past 8 years. Sex differences in migraine prevalence have been linked to menstruation, but these differences persist beyond menopause. Prevalence is highest in both males and females between the ages of 18 and 44 years and is inversely related to income and educational attainment. In the American Migraine Prevalence and Prevention Study, 93% of those with migraine reported some headache-related disability, and 54% were severely disabled or needed bed rest during an attack.[4,5] The economic burden of migraine is substantial as are the indirect costs from work-related disability and losses in productivity.[6,7] Several neurologic, psychiatric, and cardiovascular disorders, including stroke, epilepsy, major depression, sleep apnea, obesity, and anxiety, and other pain disorders, show increased comorbidity with migraine.[8,9.] Whether this relationship is causal or representative of a common pathophysiologic mechanism is unknown.

Etiology

The etiology of migraine is not entirely understood. Most clinicians now believe that the pathogenesis of migraine may be related to complex dysfunctions in neuronal and broad sensory processing.[2,8,9] However, earlier theories included hypotheses involving intracerebral arterial vasoconstriction, reactive extracranial vasodilation, in addition to neurovascular mechanisms.

The pain and symptoms of migraine are a combination of altered perceptions resulting from neural suppression and activation of subcortical structures and trigeminal systems. Migraine pain is believed to result from activity within the trigeminovascular system, a network of visceral afferent fibers that arises from the trigeminal ganglia and projects peripherally to innervate the pain-sensitive intracranial extracerebral blood vessels, dura mater, and large venous sinuses[10] (Fig. 80-1). These fibers also project centrally, terminating in the trigeminal nucleus caudalis in the brain stem and upper cervical spinal cord, and thus provide a pathway for nociceptive transmission from meningeal blood vessels into higher centers of the central nervous system (CNS). Activation of trigeminal sensory nerves triggers the release of vasoactive neuropeptides, including calcitonin gene-related peptide (CGRP), neurokinin A, and substance P, from perivascular axons. The released neuropeptides interact with dural blood vessels to promote vasodilation and dural plasma extravasation, resulting in neurogenic inflammation. Orthodromic conduction along trigeminovascular fibers transmits pain impulses to the trigeminal nucleus caudalis, where information is relayed further to higher cortical pain centers. Continued afferent input can result in sensitization of these central sensory neurons, producing a hyperalgesic state that responds to previously innocuous stimuli and maintains the headache.[9,10]

FIGURE 80-1

The pathophysiology of migraine headache. Vasodilation of intracranial extracerebral blood vessels (possibly the result of an imbalance in the brainstem) results in the activation of the perivascular trigeminal nerves that release vasoactive neuropeptides to promote neurogenic inflammation. Central pain transmission may activate other brainstem nuclei, resulting in associated symptoms (nausea, vomiting, photophobia, and phonophobia). The antimigraine effects of the 5-HT$_{1B/ID}$ receptor agonists are highlighted at areas 1, 2, and 3. (CGRP, calcitonin gene-related peptide.) *(Reprinted from*

Neurotransmission

Aura occurs in a subgroup of individuals with migraines and other primary headache disorders. The neurologic changes of the aura parallel those that occur during cortical spreading depression, a neuronal event characterized by a wave of depressed electrical activity that advances across the brain cortex, causing inflammation and activation of the trigeminal nucleus caudalis. This occurs at a rate consistent with the spread of aura symptoms.[2,9] It is not clear whether this cortical spreading depression and the aura are the substrate of pain or trigger the presentation of migraine.[9,11]

Pathophysiology

Genetic factors play an important role in susceptibility to migraine attacks. Studies in monozygotic twins suggest a 50% heritability of migraine with a multifactorial polygenic basis.[11] Although it is possible for any individual to experience a migraine attack, their abnormal recurrence can result in a diagnosis of migraine. Attack occurrence and frequency are governed by CNS sensitivity to migraine specific triggers or environmental factors. Individuals with migraine appear to have a lowered threshold of response to specific environmental circumstances resulting from genetic factors governing the balance of CNS excitation and inhibition at various levels. Thus, triggering factors modulate the genetic set point that predisposes to migraine headache.[9,11] The hyperresponsiveness of the individual's brain may be the result of an inherited abnormality in calcium and/or sodium channels and sodium/potassium pumps that regulate cortical excitability through serotonin (5-hydroxytryptamine [5-HT]) and other neurotransmitter releases. Increased levels of excitatory amino acids such as glutamate and/or alterations in extracellular levels of potassium also can affect the migraine threshold, resulting in the initiation and propagation of the phenomenon of cortical spreading depression.[11]

Serotonin (5-HT) is an important mediator of migraine headache and specific 5-HT receptor subfamilies are involved in the pathophysiology and treatment of migraine headache.[9,12] Acute antimigraine medications such as the ergot alkaloids and triptan derivatives are agonists of vascular and neuronal 5-HT$_1$ receptor subtypes, resulting in vasoconstriction of meningeal blood vessels and inhibition of vasoactive neuropeptide release and pain signal transmission.[12,13] Specifically, triptans bind nonspecifically to 5-HT$_{1B/D}$ receptors with variable 5-HT$_{1F}$ receptor affinity, resulting in direct vascular vasoconstriction. In contrast, the ditans selectively bind to 5-HT$_{1F}$ receptors without vasoconstrictive effects.[14] During a headache, CGRP is released by the trigeminal ganglion in response to vasoconstriction resulting in dilation and maintenance of cerebral blood flow.[15] By blocking CGRP release, migraine attacks can be either acutely aborted or prevented by antimigraine medications. Other medications used for migraine prophylaxis also modulate neurotransmitter systems[16] consistent with the current understanding of migraine pathophysiology and neurovascular disorders.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Migraine Headache

General

- Common, recurrent, severe headache

- Interferes with normal functioning
- Divided into two major subtypes
  - Migraine without aura
  - Migraine with aura

Symptoms

- Recurring episodes of throbbing head pain, frequently unilateral, lasting from 4 to 72 hours if left untreated
- Headaches can be severe and associated with nausea, vomiting, and sensitivity to light, sound, and/or movement, but not all symptoms are present in every attack
- Diagnostic alarms from evaluation include
  - Acute onset of the “first” or “worst” headache ever
  - Accelerating pattern of headache following subacute onset
  - Onset of headache after age 50 years
  - Headache associated with systemic illness (eg, fever, nausea, vomiting, stiff neck, and rash)
  - Headache with focal neurologic symptoms or papilledema
  - New-onset headache in an individual with cancer or human immunodeficiency virus infection

Signs

- A stable pattern, absence of daily headache
- Positive family history for migraine
- Normal neurologic examination
- Food and menstruation may serve as triggers
- Improvement in headache with sleep
- Aura can signal the migraine headache but is not required for diagnosis

Laboratory Tests

- No one test can diagnose migraine headaches
- Possible tests to consider are:
  - Serum chemistries
  - Urine toxicology profiles
  - Thyroid function tests
  - Lyme disease studies
  - Complete blood count

- Antinuclear antibody titer
- Erythrocyte sedimentation rate
- Antiphospholipid antibody titer

Diagnostic Tests

- General medical and neurologic physical examination
- Vital signs (fever, hypertension)
- Funduscopy (papilledema, hemorrhage, and exudates)
- Palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity, and cervical spine tenderness)
- Neurologic examination (identify abnormalities or deficits in mental status, cranial nerves, deep tendon reflexes, motor strength, coordination, gait, and cerebellar function)
- Consider neuroimaging studies in individuals with abnormal neurologic examination findings of unknown etiology and those with additional risk factors warranting imaging

The migraine attack is divided into several phases. *Premonitory symptoms* are experienced by up to 77% of those with migraine headaches in the hours or days before the onset of headache.[2,7] Premonitory symptoms vary widely among individuals with migraine, but usually are consistent within an individual. Neurologic symptoms (eg, allodynia, phonophobia, photophobia, hyperosmia, and difficulty concentrating) are common, but psychological (eg, anxiety, depression, euphoria, irritability, drowsiness, fatigue, hyperactivity, and restlessness), autonomic (eg, polyuria, diarrhea, and constipation), and constitutional (eg, stiff neck, yawning, thirst, food cravings, and anorexia) symptoms also are reported.[2,7] The previously popular terms *prodrome* and *warning symptoms* should generally be avoided because these are often used mistakenly to include aura.[2]

The migraine *aura*, a complex of positive and negative focal neurologic symptoms that precedes or accompanies an attack, is experienced by approximately 25% of those with migraine headaches on some occasions.[2,9] The aura typically evolves over 5 minutes or longer and lasts less than 60 minutes. Headache usually occurs within the end 60 minutes of the aura; however, sometimes aura symptoms begin at the onset of headache or during the attack. The aura is most often visual and frequently affects half the visual field.[2] Visual auras vary in their complexity and can include both positive (scintillations, photopsia, teichopsia, or fortification spectrum) and negative (scotoma and hemianopsia) features. Sensory and motor aura symptoms, such as paresthesias or numbness involving the arms and face, dysphasia or aphasia, weakness, and hemiparesis, also are reported.[2,9]

Migraine *headache* pain is usually gradual in onset, peaking in intensity over a period of minutes to hours and lasting between 4 and 72 hours. Pain can occur anywhere in the face or head but most often involves the frontotemporal region. The headache is typically unilateral and throbbing or pulsating in nature; however, pain can be bilateral at onset or become generalized during the course of an attack.[2,9] Gastrointestinal (GI) symptoms almost invariably accompany the headache. During an attack, individuals with migraine frequently experience nausea and emesis sometimes occurs. Other systemic symptoms associated with the headache phase can include anorexia, food cravings, constipation, diarrhea, abdominal cramps, nasal stuffiness, blurred vision, diaphoresis, facial pallor, and localized facial, scalp, or periorbital edema. Sensory hyperacuity, manifested as photophobia, phonophobia, or osmophobia, is reported frequently. Because headache pain usually is aggravated by physical activity, most individuals with migraine headache seek a dark, quiet room for rest and relief. Impaired concentration, depression, irritability, fatigue, or anxiety often accompanies the headache. Once headache pain wanes, individuals may experience a postdrome or *resolution phase* characterized by feeling tired, exhausted, irritable, or listless. Impaired concentration may continue, as well as scalp tenderness or mood changes. Some individuals experience depression and malaise, whereas others can feel unusually refreshed or euphoric.[2,9,17]

Diagnosis of migraine can be refined based on the frequency of monthly migraine days (MMDs) and monthly headache days (MHDs). Individuals with fewer than 15 MMDs or MHDs have episodic migraine, whereas chronic migraine is diagnosed in those with at least 15 MHDs for at least 3 months, of which at least eight are MMDs.[2,18]

Although headaches have many potential causes, most are considered primary headache disorders. A comprehensive headache history is the most essential element in establishing the clinical diagnosis of migraine.[2,8] This history should include age at onset, attack frequency and timing, duration of attacks, precipitating or aggravating factors, ameliorating factors, description of neurologic symptoms, characteristics of the headache pain (quality, intensity, location, and radiation), associated signs and symptoms, treatment history, family and social history, and the impact of headaches on daily life.

Secondary headache can be identified or excluded based on the headache history, as well as the results of general medical and neurologic examinations. Diagnostic and laboratory testing also can be warranted in the setting of suspicious headache features or an abnormal examination. Routine neuroimaging (computed tomography or magnetic resonance imaging) is generally not indicated in individuals with migraines and a normal neurologic examination but should be considered in individuals with an unexplained abnormal neurologic examination or an atypical headache history. Because migraine headaches usually begin by the second or third decade of life, those beginning after age 50 suggest an organic etiology such as a mass lesion, cerebrovascular disease, or temporal arteritis.[2,3,9] Table 80-1 lists the IHS diagnostic criteria for migraine with and without aura.[2]

TABLE 80-1

IHS Diagnostic Criteria for Migraine

Migraine without aura

At least five attacks

Headache attack lasts 4-72 hours (untreated or unsuccessfully treated)

Headache has at least two of the following characteristics:

- Unilateral location pulsating quality
- Moderate or severe intensity
- Aggravation by or avoidance of routine physical activity (ie, walking or climbing stairs)

During headache at least one of the following:

- Nausea, vomiting, or both
- Photophobia and phonophobia
- Not attributed to another disorder

Migraine with aura (classic migraine)

At least two attacks

Migraine aura fulfills criteria for typical aura, hemiplegic migraine, retinal migraine or brainstem aura

Not attributed to another disorder

Typical aura

Fully reversible visual, sensory, or speech symptoms (or any combination) but no motor weakness

Homonymous or bilateral visual symptoms including positive features (eg, flickering lights, spot, lines) or negative features (eg, loss of vision) or unilateral sensory symptoms including positive features (eg, pins and needles) or negative features (ie, numbness), or any combination

At least two of the following:

- At least one symptom that develops gradually over a minimum of 5 minutes or different symptoms that occur in succession or both
- Each symptom lasts for at least 5 minutes and for no longer than 60 minutes
- Headache that meets criteria for migraine without aura begins during the aura or follows aura within 60 minutes

Adapted from Parisi P, Belcastro V, Verrotti A, et al. "Ictal epileptic headache" and the revised International Headache Classification (ICHD-3) published in Cephalalgia 2018, vol. 38(1) 1-211: Not just a matter of definition!

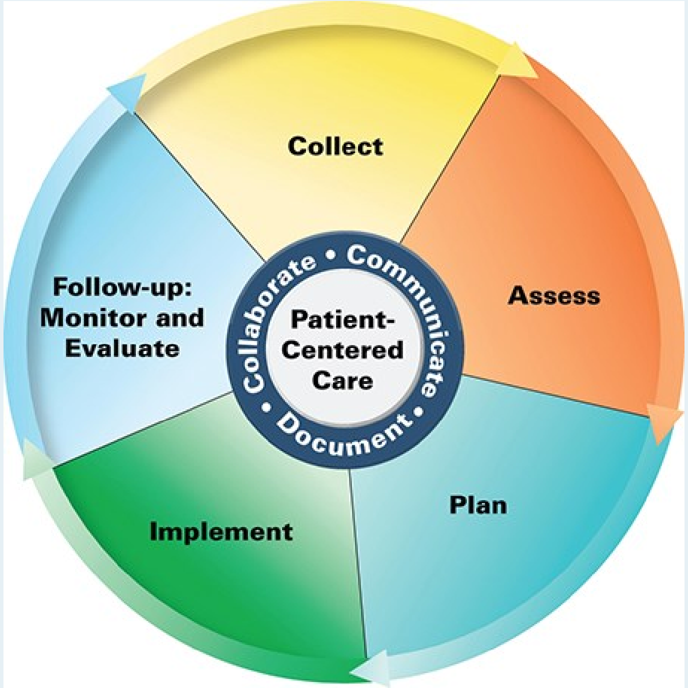
Treatment

Desired Outcome

① Clinicians who care for individuals with migraine must appreciate the impact of this painful and debilitating disorder on the life of the individual, the individual's family, and the individual's employer. Treatment strategies must address both immediate and long-term goals. Acute migraine therapies should provide consistent, rapid relief and enable the individual to resume normal activities at home, school, or work. Recurrence of symptoms and treatment-related adverse effects should be minimal. Ideally, individuals should be able to manage their own headaches effectively without a medical visit. In addition, individuals should take an active role in the creation of a long-term formal management plan. An individualized approach to treatment can result in a reduction in attack frequency and severity, thus minimizing headache-related disability and emotional distress and improving the individual's quality of life. Goals of long-term and acute treatment of migraine are listed in Table 80-2.[13,18,19]

PATIENT CARE PROCESS

Patient Care Process for Headache Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

Subjective and Objective data

- Presence of other symptoms
  - Nausea
  - Vomiting
  - Sensitivity to light, sound, and/or movement
- Identification of triggers or aura (Table 80-5)
- Patient characteristics (eg, age, sex, pregnant)

- Patient medical history (personal and family)
- Social history (smoking, diet, physical activity)
- Description of migraine/headache pain (including frequency and location)
- Presence of diagnostic alarms (see CLINICAL PRESENTATION)

Medication History

- Current use, dosage, and frequency of medications (especially over-the-counter aspirin/nonsteroidal anti-inflammatory drug [NSAID] use, herbal products, and dietary supplements) (Tables 80-3 and 80-4)

Diagnostic Tests

- Consider neuroimaging studies in individuals with abnormal neurologic examination findings of unknown etiology and in those with additional risk factors warranting imaging
- Physical Exam
- Neurological Exam
- Diagnostic abnormalities (Table 80-1)
    - Vital signs (fever, hypertension)
    - Funduscopy (papilledema, hemorrhage, and exudates)
    - Palpation and auscultation of the head and neck (sinus tenderness, hardened or tender temporal arteries, trigger points, temporomandibular joint tenderness, bruits, nuchal rigidity, and cervical spine tenderness)
    - Deficits in mental status, cranial nerves, deep tendon reflexes, motor strength, coordination, gait, and cerebellar function

Assess

Initial Assessment

- Type of headache, acute or chronic[2]
- Other contributing factors (eg, presence of anxiety, depression, or medication overuse)

Medication Assessment

- Evaluate the need for therapy
- Evaluate current therapy for appropriateness, response, adverse effects, and medication adherence
- Evaluate other therapy options (compare/contrast based on safety, efficacy, cost/coverage by insurance)

Plan*

- Acute medication therapy regimen if needed (symptomatic or abortive)
- Establish individualized treatment plan for long term
    - Nonspecific agents for mild-to-moderate attacks

  - Reserve migraine-specific agents for more severe attacks
  - Use of prophylactic agents
- Identify goals of treatment and monitoring parameters (Tables 80-2 to 80-4)
- Patient education (avoidance of triggers, headache diary, patient adherence)
- Referrals to other providers when appropriate (eg, secondary headache, psychiatry)

Implement*

- Provide patient education regarding all elements of treatment plan
- Patient education on the risk of medication as well as caffeine overuse and limits
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up, sooner if an individual is unable to perform daily activities

Follow-up: Monitor and Evaluate*

- Strive for resolution of pain (Table 80-2)
- Aim for absence of adverse effects
- Reduce headache frequency, severity, and associated-disability
- Improve quality of life
- Optimize self-care and management

**Collaborate with patients, caregiver(s), and other healthcare professionals.*

TABLE 80-2

Goals of Therapy in Migraine Management

Goals of migraine prevention
Reduce migraine frequency, severity, and disability
Reduce reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies
Improve quality of life
Prevent headache
Avoid escalation of headache medication use
Educate and enable individuals to manage their disease
Reduce headache-related distress and psychological symptoms
Goals of acute migraine treatment
Treat migraine attacks rapidly and consistently without recurrence
Restore the individual's ability to function
Minimize the use of backup and rescue medications[a]
Optimize self-care for overall management
Be cost-effective in overall management
Cause minimal or no adverse effects

[a] Rescue medications are defined as medications used at home when other treatments fail that permit the individual to get relief without a visit to the physician's office or emergency department.

Data from References [12,18,19].

General Approach to Treatment

② Nonpharmacologic and pharmacologic interventions are available for migraine management; however, medication therapy is the treatment mainstay for most individuals. Pharmacotherapeutic management can be acute (ie, symptomatic or abortive) or preventive (ie, prophylactic). Therapy decisions should consider the individual's response to specific medications, their tolerability, and coexisting illnesses that limit treatment choices. Abortive or acute therapies can be migraine-specific (eg, ergots, triptans, and CGRP antagonists) or nonspecific (eg, analgesics, antiemetics, NSAIDs, and corticosteroids). Most effective at relieving pain and associated symptoms when administered at the onset of migraine[12,13,16,18–20] (Table 80-3). An initial treatment based on headache-related disability and symptom severity is the preferred treatment strategy.[12,20] Because attack severity varies in individuals, individuals may be advised to use nonspecific agents for mild-to-moderate headaches not causing disability, while reserving migraine-specific medications for more severe attacks. The gastric stasis or nausea and vomiting that accompany migraine may compromise the absorption and efficacy of orally administered medications. Pretreatment with antiemetic agents or use of non-oral formulations (eg, suppositories, nasal sprays, or injections) is advisable when nausea and vomiting are severe.[12,20]

TABLE 80-3

Dosing of Self-Administered Acute Migraine Therapies[a]

Medication	Dose	Maximum Dose/Comments
Analgesics		
Acetaminophen[a] (Tylenol)	500-1,000 mg every 4-6 hours as needed	Maximum daily dose is 4 g
Acetaminophen 250 mg/aspirin 250 mg/caffeine 65 mg[a] (Excedrin Migraine)	Two tablets every 6 hours as needed	Available over-the-counter as Excedrin Migraine
Nonsteroidal anti-inflammatory drugs		
Aspirin[a]	500-1,000 mg every 4-6 hours as needed	Maximum daily dose is 4 g
Ibuprofen[a] (Advil, Motrin)	400-800 mg every 4-6 hours as needed	Maximum daily dose is 3.2 g
Naproxen sodium[a] (Aleve, Anaprox)	220-550 mg every 8-12 hours as needed	Avoid doses greater than 1.375 g/day
Diclofenac potassium[a] (Cataflam, Cambia)	50-100 mg every 8 hours as needed	Avoid doses greater than 150 mg/day
Ketorolac nasal (Sprix)	31.5 mg (one spray each nostril) every 6-8 hours as needed	Maximum daily dose is 126 mg/day × 5 days
Ketorolac IM[b]	30-60 mg every 6 hours as needed	Maximum daily dose is 120 mg/day × 5 days
Ergotamine tartrate		
Oral tablet (1 mg) with caffeine 100 mg[b] (Cafergot)	2 mg at onset; can repeat 1-2 mg every 30 minutes as needed	Maximum dose is 6 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Sublingual tablet (2 mg) (Ergomar)	2 mg at onset; can repeat 2 mg every 30 minutes as needed	Maximum dose is 4 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Rectal suppository (2 mg) with caffeine 100 mg[b] (Cafergot, Migergot)	Insert half to one suppository at onset; can repeat after 1 hour if needed	Maximum dose is 4 mg/day or 10 mg/week; consider pretreatment with an antiemetic
Dihydroergotamine		
Injection 1 mg/mL (D.H.E.	0.25-1 mg (IM, IV, or subcutaneous) at onset; can	Maximum dose is 3 mg/day or 6 mg/week

45)[b]	repeat every hour as needed	
Nasal spray 4 mg/mL[a] (Migranal, Trudhesa)	• One spray (0.5 mg) in each nostril at onset; can repeat sequence 15 minutes later (total dose is 2 mg or four sprays) (Migranal) • 0.725 mg (one spray) in each nostril, may repeat once in 1 hour (Trudhesa)	• Maximum dose is 3 mg/day or 6 mg/week; prime sprayer four times before using; do not tilt head back or inhale through nose while spraying; discard open ampules after 8 hours (Migranal) • Two (four sprays)/day or three (six sprays)/week (Trudhesa)
Triptans		
Sumatriptan[a]		
Injection (Imitrex, Zembrace Symtouch)	1-6 mg subcutaneous at onset; can repeat after 1 hour if needed	Maximum daily dose is 12 mg
Oral tablets (Imitrex)	25, 50, 85, or 100 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 200 mg; combination product with naproxen, 85/500 mg
Nasal spray (Imitrex)	5 or 20 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 40 mg
Nasal spray (Tosymra)	10 mg intranasally at onset; can repeat after 1 hour if needed	Maximum daily dose is 30 mg
Nasal powder (Onzetra Xsail)	22 mg (one 11-mg nosepiece in each nostril) at onset; can repeat after 2 hours if needed	Maximum daily dose is 44 mg (four nosepieces, 11 mg each)
Transdermal (Zecuity)	Apply 6.5 mg patch to upper arm or thigh over 4 hours; can apply second patch after 2 hours	Maximum daily dose is two patches
Zolmitriptan[a]		
Oral tablets/ODT (Zomig, Zomig-ZMT)	1.25, 2.5, or 5 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 10 mg; do not divide ODT dosage form
Nasal spray (Zomig)	2.5 or 5 mg intranasally at onset; can repeat after 2 hours if needed	Maximum daily dose is 10 mg
Naratriptan[a] (Amerge)	1 or 2.5 mg at onset; can repeat after 4 hours if needed	Maximum daily dose is 5 mg
Rizatriptan[a] oral tablets/ODT (Maxalt, Maxalt-MLT)	5 or 10 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 30 mg; use 5 mg dose (15 mg/day maximum) in individuals on propranolol
Almotriptan[a] (Axert)	6.25 or 12.5 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 25 mg
Frovatriptan[a] (Frova)	2.5 or 5 mg at onset; can repeat in 2 hours if	Maximum daily dose is 7.5 mg

	needed	
Eletriptan[a] (Relpax)	20 or 40 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 80 mg
Ditans		
Lasmiditan (Reyvow)	50, 100, or 200 mg at onset	Maximum of one dose per 24 hours; safety of treating more than four migraine attacks in a 30-day period has not been established
CGRP Antagonists		
Ubrogepant (Ubrelvy)	50 or 100 mg at onset; can repeat after 2 hours if needed	Maximum daily dose is 200 mg; safety of treating more than eight migraine attacks in a 30-day period has not been established
Rimegepant (Nurtec ODT)	75 mg at onset	Maximum of one dose per 24 hours; take on an empty stomach
Anti-emetics/Miscellaneous		
Acetaminophen, Isometheptene, and Dichloralphenazone (generic Midrin)	Two capsules to start followed by one capsule every hour until relief is obtained	Maximum five capsules/12 hours
Metoclopramide[b] (Reglan)	10 mg every 4-6 mg hours as needed	Maximum daily dose is 40 mg (also available as ODT)
Metoclopramide[a] and Aspirin[a]	10 mg (metoclopramide) and 1000 mg (aspirin) every 4-6 hours as needed	Maximum daily dose is 40 mg (metoclopramide) + 4 g (aspirin)
Prochlorperazine[b] (Compazine)	5-10 mg orally 3-4 times daily as needed or 25 mg via rectal suppository up to twice daily as needed	Maximum daily dose is 40 mg for oral and 50 mg for suppository
Promethazine (Phenergan)	25 mg oral or via rectal suppository every 4-6 hours as needed	Maximum daily dose is 100 mg

[a] Level A—established efficacy (≥2 Class I studies).

[b] Level B—probably effective (1 Class I or 2 Class II studies). IM, intramuscular; IV, intravenous; ODT, orally disintegrating tablet.

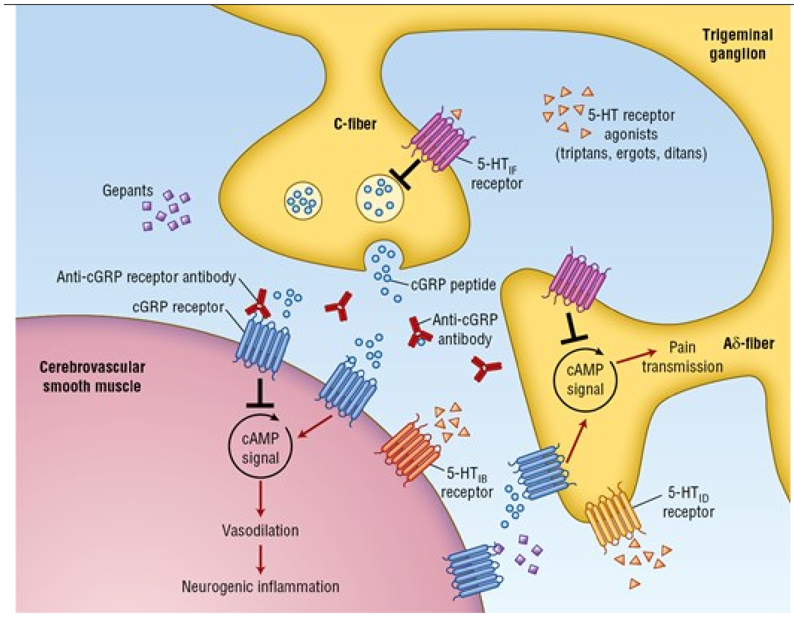
Data from References [12,19,20].

③ The frequent or excessive use of acute migraine medications can also result in *medication-overuse headache* (or *rebound headache*), characterized by increased headache frequency and medication consumption.[2,21] This syndrome evolves as a self-sustaining headache-medication cycle in which the headache returns as the medication wears off, leading to more medication consumption for relief. The headache history often reflects the gradual onset of an atypical daily or near-daily headache with superimposed episodic migraine attacks. Medication overuse is one of the most common causes of chronic daily headache.[21–23] Agents most commonly implicated include simple and combination analgesics and opiates, and triptans.[21–23] Discontinuation of the offending agent leads to a gradual decrease in headache frequency and severity and a return of the original headache characteristics. Although detoxification can be accomplished on an outpatient basis, hospitalization may be necessary for refractory rebound headache and other withdrawal symptoms (eg, nausea, vomiting, asthenia, restlessness, and agitation).[21,22] Regulation of nociceptive systems and renewed responsiveness to therapy usually occur within 2 months of medication withdrawal.[2] Most experts recommend individuals limit triptan, ergotamine, and ditan use to fewer than 10 days per month, or 2 days per week. Exceptions include limiting aspirin, acetaminophen, and NSAIDs to 15 days or less per month with recommended.[2,6,24] Those with chronic migraine may be instructed to restrict all abortive therapy to fewer than 10 days per month. Additionally, they may be advised to limit the time period in which one or more medications are regularly taken to less than 3 months to avoid the development of medication-overuse headache. One exception to this recommendation is with the CGRP antagonists, which have not caused medication-overuse headache.[25]

④ ⑤ ⑥ Preventive migraine therapies are administered daily on a routine basis to reduce the frequency, severity, and duration of attacks and improve responsiveness to symptomatic migraine therapies[26,27] (Table 80-4). Preventive therapy should be considered in the setting of recurring migraine attacks that produce significant disability despite acute therapy; for frequent attacks occurring more than twice per week with the risk of developing medication-overuse headache; for symptomatic therapies that are ineffective or contraindicated, or produce serious adverse effects; or for uncommon migraine variants that cause profound disruption and/or risk of permanent neurologic injury (eg, hemiplegic migraine, basilar migraine, and migraine with prolonged aura); and individual preference to limit the number of attacks.[18,24] Preventive therapy may also be administered preemptively or intermittently when headaches recur in a predictable pattern (eg, exercise-induced migraine or menstrual migraine).[18] The various agents used for migraine prophylaxis are reviewed. Only propranolol, timolol, divalproex sodium, topiramate, erenumab-aooe, fremanezumab-vfrm, galcanezumab-gnlm, eptinezumab-jjmr, atogepant, and rimegepant are currently FDA approved, although other agents have established or have probable efficacy for this indication.[28] Guidelines identify which agents might be effective, but the preference for one therapy over another is not advised due to lack of established results. Thus, the agent selection is based on adverse effect profiles and the individual's coexisting/comorbid conditions.[18,26,27] A therapeutic trial of 2 to 3 months is necessary to achieve clinical benefit, but reductions in attack frequency can be evident by the first month with maximal benefits observed within 6 months.[16,18,26] Medication therapy should be initiated with low doses and gradually increased to therapeutic effect or intolerable adverse effects. Doses for migraine prophylaxis are often lower than those necessary for other indications.[18,27] Overuse of acute headache medications will interfere with preventative treatment effects.[2,18] Prophylactic treatment usually is continued for at least 6 to 12 months after the frequency and severity of headaches have diminished. After that time, based on discussions with the individual, gradual tapering or discontinuation may be reasonable.[16,24–26] Many individuals with migraine headache experience fewer and less severe attacks for lengthy periods following discontinuation of prophylactic medications or taper to a lower dose. Figures 80-2 and 80-3 identify treatment and management algorithms for migraine headache.

FIGURE 80-2

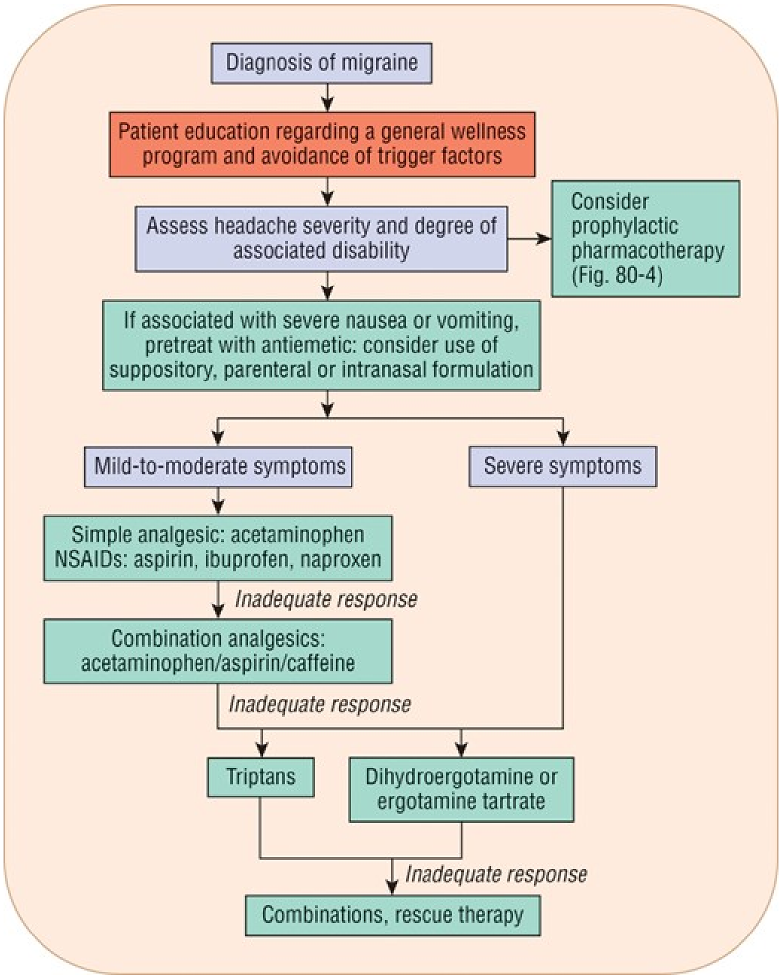
Mechanism of action of migraine medications. Nerve activity in the trigeminovascular pain pathway leads to the release of neuropeptides (ie, CGRP) and neurotransmitters (ie, serotonin and glutamate) that can hyperexcite neurons. CGRP release leads to activation of cyclic adenosine monophosphate (cAMP) signaling, which results in vasodilation of cerebrovascular smooth muscle, as well as pain signaling via Aδ fibers. Thus, injectable CGRP antagonists known as anti-CGRP antibodies bind to the CGRP receptor or CGRP ligand to block the effects of CGRP on vasodilation and neurogenic inflammation. Similarly, oral CGRP antagonists ("gepants") also inhibit the action of CGRP at the receptor. Serotonin (or serotonin agonist) binding to 5-HT receptors can inhibit presynaptic vesicular release of CGRP and inhibit postsynaptic cAMP signaling cascades.



Trigeminal ganglion
C-fiber
5-HT receptor agonists (triptans, ergots, ditans)
5-HT$_{1F}$ receptor
Gepants
Anti-cGRP receptor antibody
cGRP receptor
cGRP peptide
Anti-cGRP antibody
Cerebrovascular smooth muscle
cAMP signal
Pain transmission
Aδ-fiber
cAMP signal
Vasodilation
Neurogenic inflammation
5-HT$_{1B}$ receptor
5-HT$_{1D}$ receptor

FIGURE 80-3

Treatment algorithm for migraine headaches.



Diagnosis of migraine
Patient education regarding a general wellness program and avoidance of trigger factors
Assess headache severity and degree of associated disability
Consider prophylactic pharmacotherapy (Fig. 80-4)
If associated with severe nausea or vomiting, pretreat with antiemetic: consider use of suppository, parenteral or intranasal formulation
Mild-to-moderate symptoms
Severe symptoms
Simple analgesic: acetaminophen NSAIDs: aspirin, ibuprofen, naproxen
Inadequate response
Combination analgesics: acetaminophen/aspirin/caffeine
Inadequate response
Triptans
Dihydroergotamine or ergotamine tartrate
Inadequate response
Combinations, rescue therapy

TABLE 80-4

Dosing of Prophylactic Migraine Therapies

Medication	Initial Dose	Usual Range	Comments
β-Adrenergic antagonists			
Atenolol[a] (Tenormin)	25-50 mg/day	50-200 mg/day	
Metoprolol[b] (Toprol, Toprol XL)	25-100 mg/day in divided doses	100-200 mg/day in divided doses	Dose short-acting two to four times a day and extended-release one to two times a day
Nadolol[a] (Corgard)	40-80 mg/day	80-240 mg/day	
Propranolol[b] (Inderal, Inderal LA)	40 mg/day in divided doses	40-160 mg/day in divided doses	Dose short-acting two to three times a day and extended-release one to two times a day
Timolol[b] (Blocadren)	20 mg/day in divided doses	20-60 mg/day in divided doses	
Antidepressants			
Amitriptyline[a] (Elavil)	10 mg at bedtime	20-50 mg at bedtime	
Venlafaxine[a] (Effexor, Effexor-XR)	37.5 mg/day	75-150 mg/day	Dose short-acting two times a day and extended-release once daily
Antiseizure Medications			
Topiramate[b] (Topamax)	12.5-25 mg/day	50-200 mg/day in divided doses or only at bedtime	Increase by 12.5-25 mg/week
Valproic acid/divalproex sodium[b] (Depakene, Depakote, Depakote ER)	250-500 mg/day in divided doses, or daily for extended release	500-1,500 mg/day	Dose short-acting two times a day and extended-release once daily; monitor levels if compliance is an issue
CGRP Antagonists (Anti-CGRP Antibodies)			
Erenumab-aooe (Aimovig)	70 mg subcutaneously monthly	70-140 mg subcutaneously every month	
Fremanezumab-vfrm (Ajovy)	225 mg subcutaneously monthly or 675 mg subcutaneously every 3 months	225 mg subcutaneously monthly or 675 mg subcutaneously every 3 months	
Galcanezumab-gnlm (Emgality)	240 mg subcutaneous loading dose, followed by 120 mg subcutaneously monthly	120 mg subcutaneously every month	

Eptinezumab-jjmr (Vyepti)	100 mg via IV infusion over 30 minutes every 3 months	100-300 mg IV infusion over 30 minutes every 3 months	
CGRP Antagonists (“gepants”)			
Atogepant (Quilpta)	10 mg/day	60 mg/day	Taken with or without food
Rimegepant (Nurtec ODT)	75 mg every other day	75 mg/day	No titration required and taken on an empty stomach
Nonsteroidal anti-inflammatory drugs – *For prevention of menstrual migraine only*			
Ibuprofen[a] (Motrin)	200 mg/day in three to four divided doses	200-800 mg/day in three to four divided doses (maximum daily dose is 3200 mg)	Use intermittently only; daily or prolonged use may lead to medication-overuse headaches
Ketoprofen[a] (Orudis)	150 mg/day in divided doses	150 mg/day in divided doses	Use intermittently only; daily or prolonged use may lead to medication-overuse headaches
Naproxen sodium[a] (Aleve, Anaprox)	550 mg/day in divided doses	550-1,100 mg/day in divided doses	Use intermittently only; daily or prolonged use may lead to medication-overuse headaches
Triptans – *For prevention of menstrual migraine only*			
Frovatriptan[b] (Frova)	2.5 mg/day or 5 mg/day in divided doses; start 6 days prior to anticipated start of menstruation	5 mg/day in divided doses	Use intermittently only; daily or prolonged use may lead to medication-overuse headaches
Naratriptan[a] (Amerge)	2 mg/day in divided doses; start 6 days prior to anticipated start of menstruation	2 mg/day in divided doses	Use intermittently only; daily or prolonged use may lead to medication-overuse headaches
Zolmitriptan[a] (Zomig)	5-7.5 mg/day in divided doses; start 6 days prior to anticipated start of menstruation	5-7.5 mg/day in divided doses	Use intermittently only; daily or prolonged use may lead to medication-overuse headaches
Miscellaneous			
Histamine[a] (Histatrol)	1-10 ng 2 times/week	Same as initial dose	May cause transient itching and burning at injection site
Magnesium[a]	400 mg/day	800 mg/day in divided doses	May be more helpful in migraine with aura and menstrual migraine
MIG-99[a] (feverfew)	10-100 mg/day in divided doses	Same as initial dose	Withdrawal may be associated with increased headaches
Petasites[b]	100-150 mg/day in divided doses	150 mg/day in divided doses	Use only commercial preparations, plant is carcinogenic

Riboflavin[a]	400 mg/day in divided doses	400 mg/day in divided doses	Benefit only after 3 months

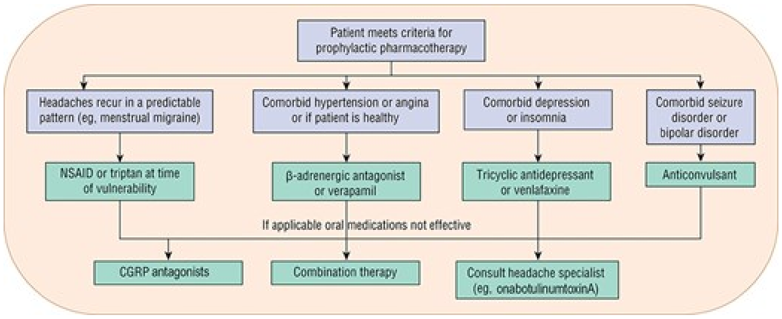
[a] Level B—probably effective (1 Class I or 2 Class II studies).

[b] Level A—established efficacy (≥2 Class I studies).

Data from References [26,28,29].

FIGURE 80-4

Treatment algorithm for prophylactic management of migraine headaches. (NSAID, nonsteroidal anti-inflammatory drug).



Patient meets criteria for prophylactic pharmacotherapy
Headaches recur in a predictable pattern (eg, menstrual migraine)
Comorbid hypertension or angina or if patient is healthy
Comorbid depression or insomnia
Comorbid seizure disorder or bipolar disorder
NSAID or triptan at time of vulnerability
β-adrenergic antagonist or verapamil
Tricyclic antidepressant or venlafaxine
Anticonvulsant
If applicable oral medications not effective
CGRP antagonists
Combination therapy
Consult headache specialist (eg, onabotulinumtoxinA)

Nonpharmacologic Therapy

⑦ Nonpharmacologic therapy of acute migraine headache is limited but can include application of ice to the head and periods of rest or sleep, usually in a dark, quiet environment. Preventative measures typically suggest individuals identify and avoid individual factors or triggers that consistently provoke migraine attacks, although some triggers are not modifiable,[2,3,18,24,30] (Table 80-5). Changes in estrogen levels associated with menarche, menstruation, pregnancy, menopause, oral contraceptive use, and other hormone therapies can trigger, intensify, or alleviate migraine.[3,31] A headache diary that records the frequency, severity, and duration of attacks can facilitate identification of migraine triggers. In appropriate situations, some individuals may learn to cope with triggers after a process of controlled exposure and approach/confront strategies.[32] Individuals also can benefit from wellness programs that include regular sleep, exercise, and eating habits, smoking cessation, and limited caffeine intake. Behavioral interventions, such as acupuncture, relaxation therapy, biofeedback (often used in combination with relaxation therapy), neuromodulation devices that use currents or magnets to modulate or change brain activity such as Cefaly® and Nerivio®, and cognitive therapy, are preventive treatment options for individuals who prefer non-medication therapy or when symptomatic therapies are poorly tolerated, contraindicated, or ineffective.[18,30,33,34] A multimodal approach with non-pharmacologic interventions has Level A evidence for migraine management and should be recommended to individuals.

TABLE 80-5

Commonly Reported Triggers of Migraine

Food triggers
Alcohol
Caffeine (greater than 200 mg/day)/caffeine withdrawal
Chocolate
Fermented and pickled foods
Monosodium glutamate (eg, in Chinese food, seasoned salt, and instant foods)
Nitrate-containing foods (eg, processed meats)
Saccharin/aspartame (eg, diet foods or diet sodas)
Tyramine-containing foods
Environmental triggers
Glare or flickering lights
High altitude
Loud noises
Strong smells and fumes
Tobacco smoke
Weather changes*
Behavioral–physiologic triggers
Excess or insufficient sleep
Fatigue
Menstruation, menopause*
Sexual activity
Skipped meals/fasting*
Strenuous physical activity (eg, prolonged overexertion)
Stress or poststress*

*Not easily modified triggers

Data from References [9,30,35].

Pharmacologic Therapy

Abortive Treatments

Analgesics and NSAIDs

Simple analgesics and NSAIDs are effective medications for managing many migraine attacks (see Table 80-3). They offer a reasonable first-line choice for mild-to-moderate migraine attacks or severe attacks that have been responsive to similar NSAIDs or nonopiate analgesics in the past. Of the NSAIDs, aspirin, diclofenac, ibuprofen, naproxen sodium, and the combination of acetaminophen plus aspirin and caffeine have established efficacy in controlled clinical trials.[12,19,20] Oral acetaminophen alone also has efficacy for non-incapacitating migraine attacks.[19] The comparable efficacy of NSAIDs and triptans in acute migraine is known, although comparisons with other therapeutic classes are limited. Baseline headache intensity does not predict aspirin or other NSAID therapy success or failure.[2,36] No studies have compared the relative efficacy of different NSAIDs.[12,20]

NSAIDs prevent neurogenically mediated inflammation in the trigeminovascular system through the inhibition of prostaglandin synthesis. Metoclopramide can speed the absorption of analgesics and alleviate migraine-related nausea and vomiting.[37] Moreover, when metoclopramide is combined with aspirin, the combination has similar efficacy to sumatriptan and is an alternative for individuals where triptans are contraindicated.[12,13] Suppository analgesic preparations are an option when nausea and vomiting are severe.[20] Acute NSAID therapy is associated with GI (eg, dyspepsia, nausea, vomiting, and diarrhea) and CNS (eg, somnolence, dizziness) adverse effects. These agents should be avoided or used cautiously in individuals with previous ulcer disease, renal disease, severe cardiovascular disease, or hypersensitivity to aspirin.[12,20]

The nonprescription combination of acetaminophen, aspirin, and caffeine was approved for migraine treatment in the United States given its efficacy in relieving pain and associated symptoms.[19,20] Aspirin and acetaminophen are also available in prescription combination products containing a short-acting barbiturate (butalbital) or narcotic (codeine). While butalbital or butalbital-containing products are possibly effective for acute migraine, these analgesics or narcotics should be limited due to overuse, medication-overuse headache, and withdrawal concerns.[19–21] Frequent consumption of aspirin or acetaminophen alone can result in medication-overuse headache, and combination analgesics appear to pose a greater risk.[21]

Triptans

The 5-HT receptor agonists, or triptans, represented a significant advance in migraine pharmacotherapy. The first member of this class, sumatriptan, and the second-generation agents zolmitriptan, naratriptan, rizatriptan, almotriptan, frovatriptan, and eletriptan are selective agonists of the 5-HT$_{1B}$ and 5-HT$_{1D}$ receptors. With these agents, relief from migraine headache results from three key actions: (1) normalization of dilated intracranial arteries through enhanced vasoconstriction, (2) inhibition of vasoactive peptide release from perivascular trigeminal neurons, and (3) inhibition of transmission through second-order neurons ascending to the thalamus.[12,20] The triptans all have established efficacy and are appropriate first-line therapy for mild to severe migraine. They are also used for rescue therapy when nonspecific medications are ineffective.[19,20]

Sumatriptan, the most extensively studied acute therapy, is available for subcutaneous, oral, and intranasal administration. Subcutaneous sumatriptan is consistently superior to placebo in alleviating migraine headache and associated symptoms, with relief reported in 70% of individuals at 2 hours.[19] It also has a more rapid onset of action when compared with the oral formulation and is packaged as an autoinjector device for self-administration. Intranasal sumatriptan provides a faster onset of effect than the oral formulation and produces similar response rates in placebo-controlled studies.[12,20]

Triptan selection is based on headache characteristics, convenience of dosing, and the individual's preference. At all marketed doses, oral triptans are effective and generally well tolerated[20] and differ in their pharmacokinetic and pharmacodynamic profiles (Table 80-6). In general, they can be divided into those with a faster onset and higher efficacy and those with a slower onset and lower efficacy. A meta-analysis summarizes the efficacy and tolerability of the oral triptans across published and unpublished studies. Using 100 mg of sumatriptan as the reference dose and based on 2-hour response rates, most of the triptans show similar therapeutic gains at manufacturer recommended doses. Exceptions to this were frovatriptan and naratriptan with lower efficacy. These agents also have the longest half-lives, the slowest onset of action, and less headache recurrence, making them more suitable for individuals who have migraine attacks with slow onset and longer duration. Faster-acting triptans are more efficacious when a rapid onset is necessary. Subcutaneous, intranasal, or orally dissolving tablets may be useful in individuals with prominent early nausea or vomiting or those who have difficulty in swallowing tablets. Most individuals prefer oral formulations even though oral absorption can be delayed during attacks.[12,20]

TABLE 80-6

Pharmacokinetic Characteristics of Triptans

medication	Half-Life (hours)	Time to Maximal Concentration (t_{max})	Bioavailability (%)	Elimination
Almotriptan	3-4	1.4-3.8 hours	80	MAO-A, CYP3A4, CYP2D6
Eletriptan	4-5	1-2 hours	50	CYP3A4
Frovatriptan	25	2-4 hours	24-30	Mostly unchanged, CYP1A2
Naratriptan	5-6	2-3 hours	63-74	Largely unchanged, CYP450 (various isoenzymes); primary sulfa medication
Rizatriptan	2-3		45	MAO-A
Oral tablets		1-1.2 hours		
Disintegrating		1.6-2.5 hours		
Sumatriptan	2			MAO-A; primary sulfa medication
Subcutaneous injection		12-15 minutes	97	
Oral tablets		2.5 hours	14	
Nasal spray		10 minutes	17	
Nasal powder		45 minutes		
Patch		1.1 hours	45	
Zolmitriptan	3		40-48	CYP1A2, MAO-A
Oral		2 hours		
Disintegrating		3.3 hours		
Nasal		4 hours		

CYP, cytochrome P450; MAO-A, monoamine oxidase type A.

Data from References [12,13,37–40].

8 Triptan clinical response can vary considerably among individuals, and responses cannot be predicted. If one triptan fails, an individual can be switched successfully to another.[12,13] After an effective agent and dose are identified, subsequent treatments with that same regimen should begin. Combination therapy may improve response rates and diminish migraine recurrence. A proprietary single tablet formulation of sumatriptan 85 mg plus naproxen 500 mg was more effective in clinical trials for headache relief and sustained pain-free response than either agent as monotherapy.[19,20]

Triptan adverse effects are common but are usually mild to moderate in nature, of short duration, and common among the class; including paresthesias, fatigue, dizziness, flushing, warm sensations, and somnolence. Local adverse effects are reported with the subcutaneous (minor injection site reactions) and intranasal (taste perversion, nasal discomfort) routes. Up to 25% of individuals report "triptan sensations," including tightness, pressure, heaviness, or pain in the chest, neck, or throat. The mechanism of these symptoms is unknown, but a cardiac source seems unlikely in most individuals; however, all triptans are partial agonists of human 5-HT coronary artery receptors in vitro, resulting in a small but significant vasoconstrictor response. Other adverse cardiac events are rare, with only isolated cases of myocardial infarction and coronary vasospasm with ischemia reported. The triptans are contraindicated in individuals with a history of ischemic heart disease (eg, angina pectoris, Prinzmetal's angina, or previous myocardial infarction), uncontrolled hypertension, and cerebrovascular disease. Individuals at risk for unrecognized coronary artery disease should use triptans with caution. Postmenopausal females, males older than 40 years of age, and individuals with uncontrolled risk factors should receive a cardiovascular assessment prior to triptan use and have initial doses administered under medical supervision. These agents are also contraindicated in individuals with hemiplegic and basilar migraine and should not be used routinely in pregnancy.[20,23]

The triptans should not be given within 24 hours of the ergotamine derivatives. Administration of sumatriptan, rizatriptan, and zolmitriptan within 2 weeks of therapy with monoamine oxidase inhibitors is not recommended. Eletriptan should not be administered with cytochrome P4503A4 (CYP3A4) inhibitors such as macrolide antibiotics, antifungals, and some antiviral therapies. Concomitant therapy with the selective serotonin reuptake inhibitors (SSRIs) or serotonin-norepinephrine reuptake inhibitors (SNRIs) (eg, duloxetine, venlafaxine, and mirtazapine) has been reported to cause serotonin syndrome based on several case reports. This interaction has been doubted as triptans are serotonin 1B and 1D agonists, whereas serotonin syndrome is hypothesized to involve 2A and 1A receptors.[41] Regulatory agencies, including the FDA, caution against concurrent administration, although it appears the likelihood of CNS adverse events is extremely low. The potential risk of these combinations should be carefully considered and discussed with the individual.[12,13,20] Frequent use of the triptans has been associated with the development of medication-overuse headache.[6,21]

Ergot Alkaloids and Derivatives

Ergotamine tartrate and dihydroergotamine can treat moderate-to-severe migraine attacks (see Table 80-4). These medications are nonselective 5-HT$_1$ receptor agonists that constrict intracranial blood vessels, centrally inhibit the trigeminovascular system, and prevent neurogenic inflammation development.[12,13] These agents also have agonist activity at dopaminergic receptors. Venous and arterial constriction occur with therapeutic doses, but ergotamine tartrate exerts more potent arterial effects than dihydroergotamine.[12,20]

The oral and rectal preparations of ergotamine tartrate containing caffeine, to enhance absorption and potentiate analgesia, are probably effective.[19] The dosage should be strictly titrated to establish an effective subnauseating dose for future attacks. The efficacy of ergotamine alone in migraine is inconsistent, despite its clinical use for decades.[12,20]

Dihydroergotamine is available for intranasal and parenteral administration by the IM, subcutaneous and IV routes and is probably effective.[13,19,20] Parenteral dihydroergotamine was previously used as an inpatient or emergency department treatment for moderate-to-severe migraine or intractable headache, but individuals can be trained to self-administer either IM or subcutaneously. Clinical studies support the nasal spray and pulmonary inhaler (still in development) as effective.[13,19]

Nausea and vomiting resulting from chemoreceptor trigger zone stimulation are among the most common ergotamine derivative adverse effects. Pretreatment with an antiemetic agent should be considered with ergotamine and IV dihydroergotamine therapy. Other common adverse effects include abdominal pain, weakness, fatigue, paresthesias, muscle pain, diarrhea, and chest tightness. Rarely, symptoms of severe peripheral ischemia (ergotism), including cold, numb, painful extremities, continuous paresthesias, diminished peripheral pulses, and claudication, can result from their vasoconstrictor effects. Gangrenous extremities, myocardial infarction, hepatic necrosis, and bowel and brain ischemia have also been reported; however, dihydroergotamine is rarely associated with such adverse effects. Triptans and ergot derivatives should not be used within 24 hours of each other,[12,20] and they are contraindicated in individuals with renal or hepatic failure; coronary, cerebral, or peripheral vascular disease; uncontrolled hypertension; and sepsis; or in individuals who are pregnant or nursing. Dihydroergotamine does not appear to cause rebound headache, but dosage restrictions for ergotamine tartrate should be strictly observed to prevent this complication.[20]

Antiemetics

Adjunctive antiemetic therapy is useful for the nausea and vomiting accompanying migraine headaches and the medications used to treat attacks (eg, ergotamine tartrate). A single antiemetic dose, such as metoclopramide or prochlorperazine, administered 15 to 30 minutes before migraine oral abortive treatment is often sufficient. Suppository preparations are available when nausea and vomiting are particularly prominent. Metoclopramide is also useful to reverse gastroparesis and improve absorption from the GI tract during severe attacks.[12]

In addition to antiemetic effects, dopamine antagonists have also been used successfully as monotherapy to treat intractable headaches (see Table 80-4). Prochlorperazine administered IV, IM, or rectal routes and IV metoclopramide provide more effective pain relief than placebo. Chlorpromazine and droperidol also provide migraine headache relief when administered parenterally at doses of 0.1 mg/kg and 2.75 to 8.25 mg, respectively. Their precise mechanism of action is unknown; however, they offer an alternative to the narcotic analgesics for refractory migraine treatment. Drowsiness and dizziness were reported occasionally, and extrapyramidal adverse effects were reported infrequently in migraine trials. Most of these medications have a risk for QT prolongation and torsades de pointes.[12,19,20]

Ditans

Lasmiditan is in a new class of abortive migraine medications known as “ditans.” Unlike the triptan mechanism of agonists at 5-HT_{1B} and 5-HT_{1D}, lasmiditan is a highly selective 5-HT_{1F} agonist whereby vasoconstrictive activity is minimized.[41] Ditans act by blocking both neurogenic inflammation in the dura and simulation of the trigeminal nucleus caudalis. In clinical trials, all doses of lasmiditan were significantly superior to placebo both for headache-free days and improvement in most bothersome symptoms (eg, nausea, phonophobia, or photophobia) 2 hours post-dose, for individuals with three to eight migraine attacks per month.[42,43] Common adverse effects reported in 2% of individuals or more were dizziness, paresthesia, sedation, and nausea/vomiting. Lasmiditan is associated with significant driving impairment where sleepiness has been reported after each dose. This adverse effect has prompted specific labeling warnings and precautions regarding not driving a motor vehicle or operating heavy machinery for at least 8 hours following each dose.

CGRP Antagonists (“gepants”)

Two small-molecule CGRP antagonists, ubrogepant and rimegepant which are also known as “gepants,” have been FDA approved for the acute treatment of migraine. During a migraine attack, CGRP levels rise resulting in vasodilation and neurogenic inflammation.[44,45] Thus, the blockade of CGRP receptors has become a breakthrough treatment for individuals with migraines. The clinical data regarding the efficacy of these medications is similar to triptans and lasmiditan, though they tend to have improved tolerability, and in contrast to triptans, the presence or history of cardiovascular disease is not a contraindication. Furthermore, medication overuse headache does not occur as a result of gepant use.[46]

The primary outcomes evaluated in clinical trials for these agents were pain freedom and reduction in most bothersome symptoms, two hours after dosing. Using these outcomes, ubrogepant (50-mg and 100-mg doses) and rimegepant (75-mg dose) have efficacy in pain freedom and freedom from most bothersome symptoms (photophobia, phonophobia, or nausea) at two hours. The incidence of adverse effects was very low (less than 5%) but included nausea for rimegepant and nausea, xerostomia, and somnolence for ubrogepant. Rimegepant is a relatively long-acting acute medication with a half-life of 11 hours, and thus, it is not recommended to repeat a dose within 24 hours. Ubrogepant has a shorter half-life of 5 to 7 hours, and the dose can be repeated two hours after the initial administration. These two medications have significant medication interactions, and concomitant use with strong CYP3A4 inhibitors, P-gp inhibitors, and BCRP inhibitors should be avoided; otherwise, dose adjustments may need to be made. Additionally, these agents should be avoided in severe renal or hepatic impairment and dose adjustments may need to be made in mild to moderate renal or hepatic impairment.

Opiate Analgesics

There is inadequate evidence supporting narcotic analgesic use (ie, parenteral butorphanol, meperidine, methadone, and tramadol or oral codeine) in the treatment of acute migraine. However, oral codeine or tramadol combinations with acetaminophen are probably effective and butorphanol nasal spray has established efficacy.[19] Opiates have no vasopressor or anti-inflammatory effects and can cause central sensitization, increasing the risk of medication-overuse headache and interfering with the efficacy of other treatments even with intermittent use.[12,19,21] These agents should generally be reserved for individuals with moderate-to-severe infrequent headaches in whom conventional therapies are contraindicated, or as “rescue medication” after individuals have failed to respond to conventional therapies. Opioid therapy should be supervised closely because of the risk of sedation and the potential for unhealthy use.[12,20]

Miscellaneous Nonspecific Medications

Corticosteroids can be considered rescue therapy for status migrainous (a severe, continuous migraine that can last up to 1 week) or to reduce migraine recurrence. Intravenous (IV) dexamethasone at a 4- to 16-mg dose has been used as an adjunct to abortive therapy, although evidence is incomplete.[19,20] IV valproate 400 to 1,000 mg also plays a role in moderate or severe intensity headaches, although data to support this is limited. When used the majority of individuals report improvement after one dose. Lastly, magnesium sulfate 1,000 to 2,000 mg IV (in migraine with aura) and generic isometheptene combinations are probably effective. A more defined role for these agents in migraine management must be established.[19]

Prophylactic Pharmacologic Therapy

Antiseizure medications

Antiseizure medications have emerged as important therapeutic options for migraine prophylaxis with valproate, divalproex, and topiramate all having established efficacy.[25] The beneficial effects of these agents are likely due to multiple mechanisms of action, including enhancement of γ-aminobutyric acid–mediated inhibition, modulation of the excitatory neurotransmitter glutamate, and inhibition of sodium and calcium ion channel activity. Antiseizure medications are particularly useful in individuals with migraine and comorbid seizures, anxiety disorder, or bipolar illness.[18,26,47,48] The use of sodium valproate and divalproex sodium (a 1:1 molar combination of valproate sodium and valproic acid) is effective based on multiple placebo-controlled studies. In most headache prophylaxis trials, there were no significant differences in treatment-emergent adverse effects between these agents and placebo. Nausea and vomiting are the most common early adverse effects but are self-limited and appear to be less common with divalproex sodium and gradual dose titration. Alopecia, tremor, asthenia, somnolence, and weight gain are also complaints.[18,26] The extended-release formulation of divalproex sodium is administered once daily and is better tolerated than the enteric-coated formulation. Hepatotoxicity is the most serious adverse effect associated with valproate, but the risk appears to be low in individuals with migraine headache (eg, individuals older than 10 years of age who are receiving monotherapy and have no underlying metabolic or neurologic disorder). Baseline liver function tests should be obtained, but routine follow-up is not necessary for asymptomatic adults on monotherapy. Regular follow-up is needed for dosage adjustments and adverse effect monitoring. Valproate when used for migraine prophylaxis, is contraindicated in pregnant individuals due to potential teratogenicity and for individuals with a history of pancreatitis or chronic liver disease.[18,26]

Topiramate is the most extensively studied antiseizure medication for migraine prophylaxis. Its efficacy shows improvements in health-related quality of life such as daily work, home, and social activities.. To minimize adverse effects, topiramate should be initiated at a low dose and slowly titrated upward. The benefits of topiramate are observed as early as 2 weeks after therapy initiation, with significant reductions in migraine frequency within the first month. Approximately half of the individuals treated to target doses are responders, defined as a 50% or greater reduction in mean headache frequency. Treatment- emergent adverse events include paresthesia, fatigue, anorexia, diarrhea, weight loss, hypesthesia, difficulty with memory, language problems, taste perversion, and nausea. Paresthesia, the most common adverse event, occurs in about half of the individuals at target doses. Weight loss, occurring in 9% to 12% of individuals, is a unique adverse effect, as weight gain is a common reason to discontinue other preventive medications. Topiramate should be used with caution or avoided in individuals with a history of kidney stones or cognitive impairment.[18,26]

Carbamazepine is possibly effective for migraine phophylasis and gabapentin has modest impact.[49] Lamotrigine is classified as possibly or probably ineffective.[26]

Additional information regarding all antiseizure medications can be found in Chapter 75, "Epilepsy."

Antidepressants

The beneficial effects of antidepressants in migraine are independent of their antidepressant activity and may be related to downregulation of central 5-HT_2 receptors resulting in increased levels of synaptic norepinephrine, and enhanced endogenous opioid receptor actions.[9] The tricyclic antidepressant (TCA) amitriptyline and SNRI venlafaxine have demonstrated efficacy in placebo-controlled and comparative studies and are classified as probably effective for migraine prophylaxis (see Table 80-4).[18,26] Use of other antidepressants is based primarily on clinical and anecdotal experience. There is neither support nor refusal regarding the efficacy of other antidepressants, such as protriptyline, fluoxetine, or fluvoxamine, for migraine prophylaxis.[26]

Anticholinergic adverse effects are common with the TCAs and limit their use in individuals with benign prostatic hyperplasia and glaucoma. Evening doses are preferred because of associated sedation. Increased appetite and weight gain can also occur. Orthostatic hypotension and slowed atrioventricular conduction are also occasionally reported.[18,26] Venlafaxine's most common adverse effects are nausea, vomiting, and drowsiness. Again, the potential risk of 5-HT syndrome should be considered in individuals using SSRIs or SNRIs along with a triptan.[20,26] Additional information about the adverse effects of antidepressants can be found in Chapter 88.

β-Adrenergic Antagonists

β-Adrenergic antagonists are among the most widely used medications for migraine prophylaxis. Metoprolol, propranolol, and timolol have established efficacy and reduce the frequency of attacks by half in more than 50% of individuals.[18,26] Atenolol and nadolol are probably effective, while nebivolol and pindolol are possibly effective (see Table 80-5).[25] Because the individual agent's relative efficacy has not been established, β-blocker selection can be based on β-selectivity, formulation, and tolerability. β-blockers may raise the migraine threshold by modulating adrenergic or serotonergic neurotransmission in cortical or subcortical pathways, although their precise mechanism is unknown. Although not first-line treatment for hypertension, β-blockers may be useful along with other therapy in individuals with comorbid hypertension or angina. Adverse effects can include drowsiness, fatigue, sleep disturbances, vivid dreams, memory disturbance, depression, impotence, bradycardia, and hypotension. The β-Blockers should be used with caution in individuals with congestive heart failure, peripheral vascular disease, atrioventricular conduction disturbances, asthma, depression, and diabetes.[18,26]

CGRP Antagonists (Anti-CGRP Antibodies)

Inhibition of the CGRP receptor is the newest target in the prophylaxis of migraine.[9,18,46,47] Several anti-CGRP receptor monoclonal antibodies have been FDA approved in recent years such as erenumab-aooe, fremanezumab-vfrm, galcanezumab-gnlm, and eptinezumab-jjmr. While erenumab targets the CGRP receptor, the others target the CGRP ligand. These biologic agents have efficacy, safety, and tolerability for the prevention of episodic and chronic migraine.[17] Erenumab, fremanezumab, and galcanezumab are all administered as monthly subcutaneous injections and fremanezumab has a quarterly (every 3 months) dosing option. Eptinezumab is a quarterly IV infusion. The lack of hepatic metabolism or renal clearance for these agents avoids medication interactions with this medication class. Injection site reactions are the most common adverse event for all of the subcutaneous agents. Constipation is reported in a small number of individuals (less than 5%) with erenumab. For eptinezumab, nasopharyngitis is reported in less than 10% of individuals and hypersensitivity is reported in less than 3%. The cost of these biological medications is higher than the oral preventive medications, and it is recommended that they are reserved for individuals who have been unable to tolerate or who did not respond to at least two of the preventive oral medications with highest level of evidence (topiramate, divalproex/valproate sodium, beta blockers, tricyclic antidepressants, or venlafaxine/duloxetine).

CGRP Antagonists ("gepants")

Unlike the large-molecule, injectable, preventative monoclonal antibodies, the "gepants" are small-molecule agents that block the ability of CGRP to bind to the CGRP docking station, which prevents prolonged migraine attacks. There are two "gepants," atogepant and rimegepant, that are FDA approved for preventative treatment of episodic migraine headaches in adults.

Atogepant (placebo, 10 mg daily, 30 mg daily, 60 mg daily) was evaluated in two, 12-week, multicenter, randomized, placebo-controlled trials for episodic migraine headache prevention.[50,51] IA decrease of approximately 4 mean migraine days a month over a 12-week period for atogepant was seen compared with a decrease of approximately 2.5 days in the placebo group. Fatigue, nausea, and constipation appeared to increase at the higher doses, and some adverse effects were noted at about 2% compared with a placebo. No liver abnormalities above the placebo rate were seen.[51] Like rimegepant and ubrogepant, atogepant has significant medication interactions, and concomitant use with strong CYP3A4 inhibitors, strong as well as moderate CYP3A4 inducers, and OATP inhibitors should be avoided; otherwise, dose adjustments may be needed. Additionally, atogepant should be avoided in severe renal or hepatic impairment. Rimegepant (75 mg every other day) was used in the prevention of episodic migraine headache for over 12 weeks in a multicenter, randomized, placebo controlled study. Overall the difference in the reduction of migraine days was 0.8 days per month with rimegepant versus placebo.[52] Two percent of adverse medication effects associated with rimegepant included nasopharyngitis, nausea, urinary tract infection, and upper respiratory tract infection were mild to moderate in severity. Adverse rimegepant effects include reversible alanine aminotransferase or aspartate aminotransferase greater than three times the upper limit of normal, reversible asymptomatic elevation of aminotransferases with alanine aminotransferase greater than ten times the upper limit of normal, and hereditary liver disorder related where bilirubin levels greater than two times the upper limit of normal.

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs are modestly effective for reducing the frequency, severity, and duration of migraine attacks, but potential GI and renal toxicity limit the daily or prolonged use of these agents. Consequently, NSAIDs have been used intermittently to prevent headaches recurring in a predictable pattern, such as menstrual migraine. NSAID administration in the perimenstrual period can be beneficial in females with true menstrual migraine. They should be initiated up to 1 week prior to the expected onset of headache and continued for no more than 10 days.[27] If long-term NSAID therapy is initiated, renal function and occult blood loss should be monitored. The evidence for efficacy is strongest for naproxen and weakest for aspirin.[27,32]

Triptans

Triptans are also useful for the prevention of menstrual migraine. Frovatriptan has established efficacy, while naratriptan and zolmitriptan are probably effective. These agents are usually started 1 or 2 days before the expected onset of headache and continued during the period of vulnerability.[27,32] Regulatory authorities are currently deliberating a separate indication for pure menstrual migraine.[26]

Miscellaneous Prophylactic Agents

At least two placebo-controlled studies show that petasites, an extract from the butterbur plant *Petasites hybridus*, is an effective preventive treatment for migraine.[18,29] There is a probable efficacy of riboflavin (vitamin B2) 400 mg daily in migraine prophylaxis, based on double-blind, placebo-controlled study.. Riboflavin is well tolerated and associated with a 50% or greater improvement in attack frequency in most individuals. However, these benefits were only significant after 3 months.[18,29] The relatively stable extract of feverfew (*Tanacetum parthenium*), MIG-99, is the most studied herbal preparation for migraine prevention and it reduces migraine frequency by almost two attacks per month and is classified as probably effective.[18,29] As CNS levels of magnesium are significantly low during migraine attacks, magnesium supplementation may be particularly effective for prevention of menstrual migraine.[31] The evaluation of various formulations of magnesium have yielded mixed results, but there is probable efficac.[18,29] Subcutaneous histamine has been compared with placebo, sodium valproate, and topiramate, with favorable results indicating probable efficacy in improving headache frequency, duration, and intensity. Transient burning and itching at the injection site were the only reported adverse effects with histamine administration.[29]

Other agents are also possibly effective for migraine prevention.[26,29] The angiotensin-converting enzyme inhibitor lisinopril and the angiotensin II receptor blocker candesartan provided effective migraine prophylaxis in recent clinical trials.[18,26] Clonidine and guanfacine also have possible efficacy, although adverse effects limit their use.[26] Coenzyme Q10 was effective for migraine prevention and well-tolerated in a small, randomized, double-blind, controlled study.[18,29] Cyproheptadine (4 mg/day) was as effective as propranolol (80 mg/day) in reducing migraine frequency, duration, and severity, while the combination was more effective in attack frequency reduction.[26,29]

The calcium channel blockers, primarily verapamil, have been widely used for preventive treatment, although the results of their use is inadequate or conflicting.[18,26] Extensive clinical experience and verapamil's ease of use suggest a possible role in migraine prevention. Adverse effects include constipation, hypotension, bradycardia, atrioventricular block, and exacerbation of congestive heart failure.[26]

Localized injections of botulinum toxin type A have been used for various conditions and pain syndromes, including chronic migraines. This agent is FDA approved for individuals who have 15 or more headache days per month lasting 4 or more hours daily. The American Academy of Neurology concludes that a 6-week trial of botulinum toxin is effective as a second-line agent after inadequate response or adverse effects to at least two of the following agents: topiramate, divalproex sodium/valproate sodium, beta-blocker, tricyclic antidepressant, or SNRI.[18]

TENSION-TYPE HEADACHE

Epidemiology

Tension-type headache is the most common type of primary headache, with an estimated 1-year prevalence of 38% to 86%.[3,53] It peaks in the fourth decade of life and is higher among females; however, the incidence decreases with age.[32] Although most individuals with tension-type headaches experience some degree of functional impairment during their attacks, few seek medical attention, likely because they have intermittent attacks. These headaches are classified as either episodic (infrequent or frequent) or chronic based on the frequency and duration of the attacks.[2] Infrequent episodic tension-type headache (defined as fewer than one episode per month) is experienced by 64% of sufferers, while 22% have a frequent episodic tension-type headache for about 1-14 days per month). The prevalence of chronic tension-type headache (defined as 15 or more days/month, perhaps without recognizable episodes) is estimated at 0.9% to 2.2%.[2,53] Risk factors associated with a poor outcome include coexisting migraine, depression, anxiety, poor stress management, and the presence of chronic tension-type headache.[55]

Pathophysiology

Although tension-type headache is the most common type of headache, it is the least studied primary headache disorder, and there is limited understanding of key pathophysiologic concepts.[2,53] Migraine and tension-type headaches represent a continuum of headache severity with similarities in mechanisms and pathophysiology. However, tension-type headache has been recognized as a distinct disorder.[2,53] The mechanism of pain in chronic tension-type headache is thought to originate from myofascial factors and peripheral sensitization of nociceptors. Central mechanisms also are involved, with heightened sensitivity of CNS pain pathways.[53] Mental stress, nonphysiologic motor stress, a local myofascial release of irritants, or a combination of these may be the initiating stimulus. Following activation of supraspinal pain perception structures, a self-limiting headache results in most individuals owing to central modulation of the incoming peripheral stimuli. Chronic tension-type headache can evolve from episodic headaches in predisposed individuals due to changes in central circuits and nociceptive processing along the brain stem reflex pathway and subsequent CNS sensitization.[53] Other pathophysiologic mechanisms also contribute to the development of tension-type headache.

Clinical Presentation

Premonitory symptoms and aura are absent with this headache, and the pain usually is mild to moderate in intensity. It is often is described as bilateral dull, nonpulsatile tightness or pressure classically described as having a "hatband" pattern.[2,53] Associated symptoms generally are absent, but mild photophobia or phonophobia may be reported. The disability associated with tension-type headache is typically minor compared to migraine headaches, and routine physical activity does not affect severity.[2,49] Palpation of the pericranial or cervical muscles can reveal tender spots or localized nodules in some individuals.[2]

Treatment

Desired Outcomes

While pain relief and prevention of further headaches are the main desired outcomes of treatment, the vast majority of episodic tension-type headache sufferers self-medicate with nonprescription medications and do not consult a healthcare professional. Although pharmacologic and nonpharmacologic treatments are available, simple analgesics and NSAIDs are the mainstay of acute therapy. Most agents used for tension-type headache have not been studied in controlled clinical trials.[54]

Nonpharmacologic Therapy

Psychophysiologic therapy and physical therapy have been used in their management. Behavioral treatments can consist of cognitive-behavioral therapy (ie, stress management), relaxation training, and biofeedback.[55] These therapies (alone or in combination with pharmacotherapy) can result in a 33% to 64% reduction in headache activity. Relaxation training combined with biofeedback is more effective than other behavioral therapy options.[55] The effect of physical therapeutic options, such as heat or cold packs, ultrasound, electrical nerve stimulation, stretching, exercise, massage, acupuncture, manipulations, ergonomic instruction, and trigger point injections or occipital nerve blocks, is somewhat inconsistent.

However, individuals may benefit from selected modalities in reducing the frequency of tension-type headache or during an acute episode.[54,55]

Pharmacologic Therapy

Simple analgesics (alone or in combination with caffeine) and NSAIDs are effective for the acute treatment of most mild-to-moderate tension-type headaches. Acetaminophen, aspirin, diclofenac, ibuprofen, naproxen, ketoprofen, and ketorolac have efficacy in placebo-controlled and comparative studies.[54] Failure of nonprescription agents can warrant therapy with prescription medications. The combination of aspirin or acetaminophen with butalbital or, rarely, codeine can be effective options in selected individuals; however, use of butalbital and codeine combinations should be avoided when possible owing to the high potential for overuse and unhealthy use.

Acute medications should be taken for episodic tension-type headache no more than 10 days a month for butalbital-containing or combination analgesics, or 15 days a month for NSAIDs. This practice helps prevent the development of medication-overuse or chronic tension-type headache.[54] The efficacy of muscle relaxants in episodic tension-type headache management is not known.[2,54] Preventive treatment is appropriate for most individuals with chronic tension-type headache and should be considered in those whose episodic headache occur more than twice per week, last more than 3 to 4 hours, or their severity results in medication overuse or substantial disability.[55]

Preventive treatment for tension-type headaches is similar to migraine headaches. The TCAs are prescribed most often for prophylaxis, but other medications can also be selected after considering comorbid medical conditions and medication adverse effect profiles. In general, the SSRIs are only effective in individuals with tension-type headache and depression, and limited studies support the mirtazapine and venlafaxine use in individuals with chronic tension-type headache without depression.[55] Topiramate, gabapentin, and tizanidine may have benefits in chronic tension-type headache; however, randomized clinical trials need to be done. Lidocaine trigger point injections may reduce headache frequency for frequent episodic or chronic tension-type headache. Injection of botulinum toxin into pericranial muscles has inconsistent efficacy in the prophylaxis, and because of this, it is of uncertain benefit.[55]

CLUSTER HEADACHE

Epidemiology

Cluster headache is the most severe of the primary headache disorders and is characterized by attacks of excruciating, unilateral head pain that occur in series lasting for weeks or months. These cluster periods are separated by remission periods, usually lasting months or years.[2,56] These headaches can be episodic or chronic,[2] and are relatively uncommon among the primary headache disorders. However, the exact prevalence is uncertain. Estimates from pooled population studies show a lifetime prevalence of 124 per 100,000 or 0.12%.[56,57] The male-to-female ratio for cluster headache is approximately 4:1 with onset typically in the second to third decade of life. Up to 85% of individuals with cluster headaches are tobacco smokers or have a smoking history. Tobacco cessation, however, does not seem to improve the course of headaches. Recent genetic epidemiologic surveys support a predisposition for cluster headache in certain families.[56–58]

Pathophysiology

The etiologic and pathophysiologic mechanisms of these headaches are not entirely understood. Neuroimaging studies performed during acute attacks show activation of the ipsilateral hypothalamic gray area, implicating the hypothalamus as a modulator. The hypothalamus secondarily activates trigeminal-autonomic reflexes, leading to the ipsilateral pain and cranial autonomic features characteristic of cluster headache.[56–58] The cyclic and circadian rhythmicity of attacks also implicates pathogenesis of hypothalamic dysfunction.[57,58] Cluster headache may result from inflammation of the nerves traversing the cavernous sinus resulting in injury to sympathetic fibers of the internal carotid artery.[57]

Clinical Presentation

One hallmark of cluster headaches is the circadian rhythm of painful attacks. Episodic cluster headaches are the most common cluster headache subtype, occurring in up to 90% of individuals.[57] These episodic attacks occur daily for a week to several months, followed by long pain-free intervals. Headache remission averages 2 years in length but can range from 2 months to 20 years in duration. Approximately 15% of individuals have chronic symptoms with attacks recurring for over 1 year without remission or with remission periods lasting less than 1month.[56,57]

Cluster headache attacks occur commonly at night and frequently in the spring and fall. These attacks occur suddenly and pain peaks quickly after onset. The pain is excruciating, penetrating, and of a boring (ie, deep, non-pulsating, behind the eye) intensity in orbital, supraorbital, and temporal unilateral locations. They generally lasts 15 to 180 minutes and are accompanied by cranial autonomic symptoms such as conjunctival injection, lacrimation, nasal stuffiness, rhinorrhea, eyelid edema, facial sweating, and miosis/ptosis. Most sufferers also describe restlessness or agitation; however, all of these symptoms resolve when the headache ceases. While individuals with migraine retreat to a quiet, dark room, individuals with cluster headache generally sit and rock or pace about the room clutching their head. Auras are not present and during the cluster period, attacks occur from once every other day to eight times per day.[56,57] Specific diagnostic criteria for cluster headaches are provided within the IHS classification system.[2]

Treatment

Desired Outcomes

As in migraine, therapy for cluster headaches involves both abortive and prophylactic therapy with the overall desired outcomes being resolution or prevention of pain and disability. Abortive therapy is directed at managing the acute attack, whereas prophylactic therapies are started early in the cluster period in an attempt to induce remission. Individuals with chronic cluster headache can require prophylactic medications indefinitely.

Abortive Therapy

Oxygen

The standard acute treatment of cluster headache is inhalation of 100% oxygen by a nonbreather facial mask at a rate of at least 12 to 15 L/min, with effects usually starting 15 to 20 minutes after treatment.[58–61] Repeat or frequent administration over a short period of time should be avoided, as overuse may increase the frequency or merely delay rather than abort the attack in some individuals.[59,60] No adverse effects have been reported with the use of oxygen, but caution should be used for those who smoke or have chronic obstructive pulmonary disease.

Triptans

The quick onset of subcutaneous and intranasal triptans makes them safe and effective abortive agents for cluster headaches. Subcutaneous sumatriptan (6 mg) is the most effective agent, whereas nasal sprays, which are less effective than subcutaneous administration, may be better tolerated in some individuals. Adverse events reported with triptan use in individuals with cluster headache are similar to those seen in individuals with migraine. Orally administered triptans have limited use in cluster attacks because of their relatively slow onset of action; oral zolmitriptan (10 mg), however, was modestly effective in individuals with episodic cluster headache.[55]

Ergotamine Derivatives

All forms of ergotamine have been used in cluster headaches, although no controlled clinical trials support their use.[38,39] In clinical use, IV dihydroergotamine may be given as a bolus followed by repeated administration over several days to break the cycle of frequent attacks. In addition, ergotamine tartrate has provided effective relief from cluster headache attacks when administered sublingually.[59] Dosing guidelines are similar to those for migraine headache therapy.

Prophylactic Therapy

Verapamil

The preferred first-line treatment for cluster headaches prevention is verapamil, a calcium channel blocker with antianginal and antiarrhythmic properties.[58,60,61] Its beneficial effects often appear within 2 to 3 weeks of therapy, starting with a dose of 240 mg/day, titrated to a target dose of 360 to 960 mg/day. Rarely, individuals with refractory cluster headaches require doses as high as 1,200 mg/day. In such individuals, an electrocardiogram should be obtained as the dose is increased, due to concerns for bradycardia or heart block.[59,61]

Galcanezumab

Galcanezumab is a monoclonal antibody that binds to the CGRP ligand that FDA approved for episodic cluster headache. It has a modest benefit in reducing the number of cluster headaches per week for one to three weeks for individuals with episodic cluster headaches in a randomized controlled trial. Galcanezumb is dosed subcutaneously (300 mg) at the onset of the cluster period, and then continued monthly until the end of the cluster period. It should be reserved for individuals with prior episodic cluster headache periods lasting longer than 1 month when first-line preventive medications are ineffective, poorly tolerated, or contraindicated. It was well tolerated with injection site reaction (less than 10%) being the most frequently reported adverse event.[62]

Lithium

Lithium carbonate is effective for episodic and chronic cluster headache attacks and can be used when other medications are ineffective or contraindicated. A positive response is seen in up to 78% of individuals with chronic cluster headache, and in up to 63% of individuals with episodic cluster headache. The usual dose is 600 to 1,200 mg/day, with a suggested starting dose of 300 mg twice daily. Lithium levels should be monitored and maintained between 0.4 and 1.2 mEq/L (mmol/L).[59]

Major adverse effects include tremors, thyroid, and renal dysfunction, and rarely cardiac arrhythmias. Liver, thyroid, and renal function must be carefully monitored during therapy. Lithium should be administered with caution to individuals with significant renal or cardiovascular disease, dehydration, pregnancy, or concomitant diuretic or NSAID use.[59,61] Additional details regarding lithium administration can be found in Chapter 86, "Substance Use Disorders II: Alcohol Nicotine and Caffeine."

Corticosteroids

Corticosteroids can be used effectively for inducing cluster headache remission, although clinical trial data are lacking.[59] Therapy is initiated as 60 to 100 mg/day prednisone for 5 days and then tapered by approximately 10 mg/day. Long-term use is generally not recommended to avoid steroid-induced complications, and headaches can recur when therapy is tapered or discontinued.[59,61]

Miscellaneous Agents

Other therapies used in the acute management of cluster headache include intranasal lidocaine and subcutaneous octreotide. There is limited support for the use of topiramate, divalproex sodium, melatonin, indomethacin, long-acting triptans, and intranasal capsaicin for cluster headache prevention.[59–61]

For individuals refractory to pharmacologic therapy, neurosurgical interventions to relieve debilitating chronic cluster headaches may be considered.[59] Neurostimulation has gained attention in the last several years, and vagal nerve stimulation and sphenopalatine stimulation have positive results in small clinical trials.[58,59,63]

EVALUATION OF THERAPEUTIC OUTCOMES

Pharmacologic treatment should occur with medications that have the highest level of efficacy and management should be individualized based on the individual's clinical presentation and medical history, using the lowest effective doses titrated to clinical benefit and absence of adverse events. Avoid medications that increase headache frequency or severity. Nonpharmacologic or nonprescription treatments for headache management can be used either before or concurrently with other pharmacologic therapy. However, individuals may not know how to use these products optimally and often need instructions and dosing limits.

Analgesics and NSAIDs are considered the medications of choice for infrequent mild-to-moderate and severe attacks. The triptans or dihydroergotamine can be used if initial therapies prove ineffective or as first-line therapy in moderate-to-severe migraine headache. Abortive therapy should be instituted early in the course of the attack to optimize efficacy and minimize migraine-related pain and disability. Preventive therapy should be considered for recurring migraine attacks that produce significant disability or frequent attacks requiring symptomatic medication more than twice per week. Additionally, preventative therapy should be considered if symptomatic therapies that are ineffective or contraindicated or produce serious adverse effects and in the case of uncommon migraine variants that cause risk of neurologic injury. The efficacy of any prescribed prophylactic regimen should be periodically assessed for efficacy and adverse effects. Therapeutic interventions require an adequate trial to achieve clinical benefit, and maximal benefit may not be seen for 6 months or more. A prolonged headache-free interval could allow for gradual dosage reduction and discontinuation of therapy.

Monitor individuals for headache frequency, intensity, and duration, as well as any change in the headache pattern. To this end, they should be encouraged to keep a headache diary, documenting the frequency, severity, and duration of attacks and response to medication and potential trigger factors. Careful monitoring is essential to initiate the most appropriate pharmacotherapy, document therapeutic successes and failures, identify medication contraindications, and prevent or minimize adverse events. Individuals using acute therapies should be monitored for prescription and nonprescription medication use frequency to identify potential medication-overuse headache.

Although migraine is widely recognized as a disease that exacts an enormous toll on the sufferer, healthcare providers often do not recognize the degree and scope of functional impairment imposed on the individual. Approximately one out of every six healthcare visits for migraine occurs in the emergency department, although management in this setting is often suboptimal. The use of opioids for the acute migraine treatment in the emergency department is increasing, and the likelihood of unnecessary radiation exposure is greater.[5] Although most episodic migraine sufferers take medications for their headaches, only two-thirds of individuals who have been diagnosed consult with a healthcare provider regarding use of migraine-specific treatments. Just 11% of those eligible for medications to prevent migraines currently use them, although approximately 38% would benefit from prophylaxis.[14] Patient counseling is necessary to allow for proper medication use (eg, self-injection with sumatriptan), to encourage medication use early in the headache cycle, and enhance individual compliance. Strict adherence to dosing guidelines should be stressed to minimize potential toxicity. Patterns of abortive medication use should be documented to establish the need for prophylactic therapy. Prophylactic therapies also should be monitored closely (every 3-6 months until stable) for adverse reactions, abortive therapy needs, adequate dosing, and compliance. Since many individuals with migraine who receive inadequate care experience substantial levels of pain and disability, improvement in migraine diagnosis, care, and treatment potentially could result in lower direct and indirect disease costs. Consultation with other healthcare practitioners should be encouraged when changes in headache patterns or medication use occur.

CONCLUSION

Even though headache disorders result from neuronal dysfunction, the precise etiology and nature of the dysfunction are unknown. Serotonergic neurotransmission and the trigeminovascular system appear to play important roles. A careful individual workup, including patient history, physical examination, and appropriate laboratory tests, should identify most headache individuals with major disease. Various strategies can help manage migraine, tension-type, and cluster headaches to suppress acute attacks and prevent recurrences. Continuing research in existing and newly identified pathways will better define pathophysiologic mechanisms and aid the search for less toxic and more efficacious pharmacologic agents.

ABBREVIATIONS

5-HT	5-hydroxytryptamine
CGRP	calcitonin gene-related peptide
CNS	central nervous system
CYP	Cytochrome P450
FDA	Food and Drug Administration
GABA	γ-aminobutyric acid
GI	gastrointestinal
5-HT	serotonin, 5-hydroxytryptamine
IHS	International Headache Society
IM	intramuscular
IV	intravenous
MHD	monthly headache days
MMD	monthly migraine days
NSAIDs	nonsteroidal anti-inflammatory drugs
OATP	Organic anion transporting polypeptides
ODT	Orally disintegrating tablet
OTC	over the counter
SNRI	serotonin-norepinephrine reuptake inhibitor
SSRI	selective serotonin reuptake inhibitor
TCA	tricyclic antidepressant

SELF ASSESSMENT QUESTIONS

1. Which one of the following is NOT a type of primary headache disorder?
   A. Migraine
   B. Tension
   C. Cluster
   D. Vascular
2. Migraine pain is believed to result from activity in which one of the following systems?
   A. Perivascular
   B. Trigeminovascular
   C. Extravascular
   D. Tuberofundibular
3. The migraine aura is defined by which one of the following?
   A. Positive focal neurologic symptoms that follow an attack
   B. Negative focal neurologic symptoms that precede an attack
   C. Positive and negative focal neurologic symptoms that follow an attack
   D. Positive and negative focal neurologic symptoms that precede or accompany an attack
4. Migraine aura typically lasts:
   A. Less than 20 minutes
   B. Less than 60 minutes
   C. More than 60 minutes
   D. More than 120 minutes
5. Which one of the following is *not* part of International Headache Society diagnostic criteria for migraine without aura?

A. At least two attacks

B. Headache that lasts 4 to 72 hours (untreated or unsuccessfully treated)

C. At least two of the following characteristics: unilateral location, pulsating quality, moderate or severe intensity, aggravation by or avoidance of routine physical activity

D. During headache at least nausea, vomiting, or both or photophobia and phonophobia

6. Which one of the following drug or drug classes is *not* used in the acute treatment of migraine headaches?

A. Ergot alkaloids

B. Antidepressants

C. NSAIDs

D. Serotonin agonists

7. Individuals may benefit from adherence to a wellness program that may include all of the following *except*:

A. Regular exercise

B. Regular eating habits

C. Smoking cessation

D. Increasing caffeine intake

8. Medication-overuse headache is commonly implicated with the use of all of the following *except*:

A. Simple analgesics

B. CGRP antagonists

C. Opiates

D. Triptans

9. Which of the following is the most common adverse effect of the ergotamine derivatives?

A. Painful extremities

B. Peripheral ischemia

C. Nausea and vomiting

D. Continuous paresthesias

10. Which of the following preventive treatments for migraine is associated with weight loss?

A. Propranolol

B. Divalproex sodium

C. Topiramate

D. Amitriptyline

11. Which one of the following oral triptans has the longest half-life, but the slowest onset of action?

    A. Sumatriptan

    B. Eletriptan

    C. Naratriptan

    D. Frovatriptan

12. Which triptan has established efficacy in migraine prevention?

    A. Naratriptan

    B. Sumatriptan

    C. Frovatriptan

    D. Eletriptan

13. Which of the following would *not* be appropriate for migraine prophylaxis?

    A. Metoprolol

    B. Acebutolol

    C. Atenolol

    D. Propranolol

14. Which of the following medications does *not* target calcitonin gene-related peptide?

    A. Galcanezumab

    B. Ubrogepant

    C. Lasmiditan

    D. Eptinezumab

15. Which of the following vitamins has evidence to support efficacy in migraine prevention?

    A. Ascorbic acid

    B. Riboflavin

    C. Cyanocobalamin

    D. Pyridoxine

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Vascular headache is an outdated term that is not considered a primary headache disorder. The other options listed are primary headache disorders. See “Etiology“ section.

2. **B.** Migraine pain is associated with the trigeminovascular system that includes neurons in the trigeminal nerve and the cerebral blood vessels they innervate. See “Etiology“ section under “Migraine.”

3. **D.** Migraine aura may include positive and negative neurologic symptoms that occur *before* or *during* a migraine attack. See “Clinical Presentation“ section under “Migraine.”

4. **B.** Headache usually occurs within 60 minutes of the end of the aura. See “Clinical Presentation“ section under “Migraine.“

5. **A.** Minimum criteria include at least *five* attacks. See Table 80-1.

6. **B.** Antidepressants are not used for the acute treatment of migraine; they may be used for preventive therapy or for secondary psychological symptoms. See “Prophylactic Pharmacologic Therapy“ section under “Migraine.”

7. **D.** Caffeine is a stimulant that could potentially worsen or exacerbate migraine. Regular exercise, proper diet, and smoking cessation may be beneficial for individuals with migraines. See “Nonpharmacologic Therapy" section under “Migraine."

8. **B.** Agents most commonly implicated in medication-overuse headache include simple and combination analgesics, opiates, and triptans. CGRP antagonists have not been associated with medication-overuse. See “Abortive Treatments“ section under “Migraine.“

9. **C.** The use of ergotamine derivatives is most commonly associated with gastrointestinal adverse effects. These effects result from the stimulation of the chemoreceptor trigger zone. See “Ergotamine Derivatives“ section.

10. **C.** Topiramate can lead to weight loss in approximately 10% of individuals, while some other prophylactic agents, especially divalproex, can cause weight gain. See “Antiseizure Medications“ section.

11. **D.** Frovatriptan has a long half-life of 25 hours, and an onset action of up to 4 hours when compared to other agents in the same class. See Table 80-6.

12. **C.** Frovatriptan has established efficacy, particularly in the prevention of menstrual migraine. Naratriptan and zolmitriptan are probably effective. See “Triptans“ section.

13. **B.** Acebutolol is a selective beta antagonist that would not be as likely to prevent migraine attacks. Metoprolol, atenolol, and propranolol would be more appropriate choices. See “β-Adrenergic Antagonists“ section.

14. **C.** Lasmiditan is a 5-HT$_{1F}$ receptor agonist, while galcanezumab and eptinezumab are CGRP monoclonal antibodies and ubrogepant is a CGRP antagonist. See “Pharmacologic Therapy“ section.

15. **B.** Riboflavin has probable efficacy in migraine prophylaxis; however, the benefits of therapy became significant only after 3 months. See Table 80-4.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 82: Attention Deficit Hyperactivity Disorder

Danielle L. Stutzman; Julie A Dopheide; Steven R. Pliszka

KEY CONCEPTS

KEY CONCEPTS

① Untreated or ineffectively treated childhood attention deficit/hyperactivity disorder (ADHD) can lead to poor school performance, poor socialization, and increased risk for traffic accidents, psychiatric comorbidities, unemployment, and involvement with the criminal legal system during adolescence and adulthood.

② ADHD is 74% genetic in origin and is associated with decreased brain volume, a delay in cortical maturation, and possible dysregulation of the “default mode network,” a brain system that regulates attention, prioritization of information, memory, and impulse control.

③ To meet *DSM-5* diagnostic criteria for ADHD, symptoms of inattention or hyperactivity-impulsivity, separately or all together, must be present during childhood and cause functional impairment in two different settings for 6 months . Adult-onset ADHD requires further study.

④ Physical, mental health, and psychiatric comorbidities must be assessed, prior to initiating pharmacotherapy, and the goals of treatment must be set.

⑤ Preschoolers, school-age children, adolescents, and adults with ADHD all can benefit from nonpharmacologic interventions that include a healthy diet, education on ADHD, and potentially effective educational, cognitive, and behavioral treatments.

⑥ The stimulants are the most effective pharmacologic treatment option for all ages with a rapid therapeutic effect, typically within 1 or 2 hours of an effective dose. Methylphenidate is recommended as first-line for children and adolescents while amphetamines are first-line treatment for adults based on efficacy and tolerability.

⑦ Alpha-2 adrenergic agonists such as extended-release preparations of guanfacine and clonidine are less effective than stimulants as monotherapy and are used in combination with stimulants or as monotherapy in youth to improve symptom control, particularly oppositional behaviors and insomnia.

⑧ When ADHD coexists with other neuropsychiatric conditions, such as anxiety disorders, major depression, autism spectrum disorder (ASD), or Tourette disorder, it is optimal to treat the most functionally impairing disorder first (whether it is ADHD or the co-occurring condition) and then treat the second disorder.

⑨ When ADHD coexists with bipolar disorder, it is necessary to first stabilize the mood with lithium, an antiseizure medication (or mood stabilizer), or a second generation antipsychotic before adding an ADHD-specific medication such as a stimulant.

⑩ Atomoxetine is a good option to manage ADHD symptoms in adolescents or adults with substance use disorders or when stimulants are intolerable. It has a delayed onset of effect (2–4 weeks) and has no potential for physical dependence. Viloxazine has similarities with delayed onset and also lacks physical dependence potential, but it requires further study compared to atomoxetine and stimulants to fully assess its place in therapy.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the approximately 7-minute video (Video link) by an ADHD researcher and a child psychiatrist, Dr. Steven R. Pliszka, as he provides an example of a typical interview with a child undergoing evaluation for ADHD and he discusses the clinical assessment of ADHD. An ADHD diagnostic rating tool is used to collect and document information from the child utilized in the diagnostic assessment. Versions of validated diagnostic rating tools for parents and teachers are routinely utilized for diagnostic formulation as well. The video is useful to enhance student understanding regarding the COLLECT and ASSESS steps in the patient care process for managing ADHD.

INTRODUCTION

Once considered primarily a childhood disorder, attention deficit/hyperactivity disorder (ADHD) is now known to persist into adolescence for 75% and into adulthood for approximately 50% of individuals.[1,2] The American Academy of Pediatrics (AAP) considers ADHD a chronic condition that requires ongoing management.[3–5] ADHD has been correlated with neuroanatomical and functional brain changes that functionally result in inattention, impulsivity, and hyperactivity.[6,7] It is unusual for an individual to display signs of the disorder in all settings or even in the same setting at all times; however, there is a persistent pattern of symptoms that continues for 6 months or more.[1,7] Co-occurring anxiety, mood disorders, learning disabilities, medical conditions, and substance use disorders (SUDs) must be considered during assessment and treatment. Behavioral interventions and medications are effective for all ages, but there are special treatment plan considerations when developing and monitoring each age group.[3–5,8]

① The psychiatric assessment of a child requires obtaining information from the child, parents, caregivers, and teachers.[1,5,9] Treating children with psychotropic medications requires a different approach than treating adults. Children undergo neurologic, physiologic, and psychosocial changes throughout development. Age-related pharmacodynamic and pharmacokinetic differences can alter drug disposition and response. Psychotropic medication treatment of children is intended to control symptoms or behaviors that impair learning and development.[1,5,9] Children may not be able to articulate symptom response or adverse effects of a medication. Adolescents and adults with ADHD may not have been diagnosed and treated during childhood, putting them at greater risk for the psychosocial consequences of ADHD, including unemployment, unstable relationships, substance abuse, and incarceration.[1,2,5,10,11]

EPIDEMIOLOGY

ADHD is the most well-known and researched neurodevelopmental disorder of childhood and occurs in approximately 5% to 10% of children and approximately 2.5% to 5% of adults.[12–14] Non-Hispanic Caucasian and African-American children are more likely diagnosed with ADHD compared with children of Hispanic or Asian descent according to CDC and National Children's Health survey data.[12,15] It is more prevalent in males than females with a ratio of 2:1 in children and 1.6:1 in adults.[1] In 2016, 6.1 million children in the United States or 9.4% of those aged 2 to 17 years were diagnosed with ADHD: almost twice the actual rate according to worldwide prevalence studies and the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*).[1,5,16] Methodological inconsistencies in diagnostic assessments likely contribute to increasing diagnosis and differences in prevalence rates internationally. Investigators evaluating 135 ADHD prevalence studies representing seven regions (North America, South America, Europe, Asia, Africa, Oceania, and the Middle East) found when consistent diagnostic criteria from the *DSM-5* are applied, the prevalence of ADHD for children and adolescents is similar among countries globally, at approximately 5.5%.[5,13,14,16] There is increasing concern among healthcare professionals and the public regarding the overdiagnosis of ADHD leading to stigmatization and potentially inappropriate treatment.[5]

Increasing rates of ADHD diagnosis in the United States is likely a factor associated with the observed increased prescribing of ADHD medications. In 2016, the US Centers for Disease Control (CDC.gov) reported that 2 million of the 6.1 million children with ADHD were first diagnosed at 2 to 5 years of age.[12,16] Of concern is the mode of treatment for these toddlers, as CDC data showed three out of four 2- to 5-year-olds with ADHD were prescribed medications and only one out of two were prescribed behavioral interventions. The AAP recommends a 6-month trial of behavioral classroom interventions and parent training in behavioral management prior to pharmacotherapy in children less than 6 years old.[12,16] In addition to young children, adolescents and young adults are increasingly being diagnosed with ADHD. A large US pharmacy benefits management company, Express Script's, analysis of pharmacy claims representing 400,000 privately insured individuals younger than 65 years, showed that ADHD medication use increased by 35.5% for all age groups between 2008 and 2012. In addition, while the number of adults using ADHD medications was up 53.4% from 2008 to 2012, children still received a higher percentage of ADHD prescriptions compared to adults and 80% of these were stimulants.[17] In 2015, 4% of privately insured females ages 15 to 44 filled a prescription for an ADHD medication, most often a stimulant such as amphetamine salts or methylphenidate. This represents a 344% increase in ADHD medication prescribing in 2015 compared to 2003. Over the same time period, filled prescriptions for nonstimulant ADHD medications did not increase.[18]

Therefore, healthcare professionals and teachers should recommend a thorough assessment of ADHD by an experienced clinician using standardized criteria and investigating all possible causes of inattention, impulsivity, and hyperactivity in order to avoid overdiagnosis and potentially inappropriate treatment.

ETIOLOGY AND PATHOPHYSIOLOGY

② There has been substantial progress in understanding the role of both genetics and the environment, as well as their interaction, in the pathophysiology of ADHD. An extensive review of twin studies over the past 40 years has shown that the heritability of ADHD (the amount of variance in ADHD symptoms attributable to genetics) averages around 74%.[19] The most extensive genome-wide association study (GWAS) to date was a meta-analysis of 12 studies comparing 20,183 persons with ADHD and 35,191 controls.[20] This study discovered 12 regions that achieved genome-wide significance with *none* of the genes identified in previous candidate gene studies (ie, dopamine transporter) being significant.[19] It remains to be seen exactly how the newly identified genes might be involved in ADHD. Despite the size of the study, all 12 loci identified accounted for only 22% of the genetic variance as the remaining ~50% of the heritability is "missing."[19]

Some of the missing heritability may occur because patients have copies or deletions in the genome that cover multiple genes called copy number variants (CNVs). Current CNV studies have implicated a number of systems in ADHD: cholinergic receptors and genes for central nervous system (CNS) development[21] and an area of chromosome 15q13.[22] The CNVs affecting the metabotropic glutamatergic receptor 5 gene were enriched in cohorts of patients with ADHD relative to controls.[23]

Increasingly, there is clear evidence that genes involved in ADHD are also involved in other major psychiatric disorders, including schizophrenia, and affective (mood) disorders.[25] A significant genetic correlation has been found between ADHD and autism spectrum disorder (ASD) in a large GWAS of individuals with ASD.[26] Thus, genes for neurodevelopmental disorders are not specific to ADHD and may show considerable pleiotropy (one gene influences two or more seemingly unrelated phenotypic traits).[27]

Since gene by environment interaction may also be important, it is critical to examine environmental factors. Twin studies can estimate the amount of variance related to the environment and further subdivide environmental effects into "shared" (an event both twins experience, such as neighborhood) and "non-shared" (one twin has a head injury, the other does not). Surprisingly, shared environmental factors do not appear to have a relationship to ADHD symptoms.[28] In an Australian population-based control study, over 12,000 children with ADHD were compared to over 30,000 controls on maternal, pregnancy, and birth data.[29] Mothers of children with ADHD were significantly more likely to be younger, single, or to have smoked in pregnancy. Additionally, they had a higher level of induced labor, preterm labor, preeclampsia, or early term delivery. Antidepressant use in pregnancy is not related to ADHD,[30] and in an extensive review of prenatal factors in ADHD, Sciberras et al.[31] noted that carefully done prospective studies are needed to determine causality of these factors.

② Genetics and environment work together to shape the brain, and there is an emerging picture of differences in brain structure, function, and connectivity that occur across the life span in individuals with ADHD. Cortical surface area is reduced in ADHD versus controls in both childhood and adulthood; in addition, the age of peak thickness occurs later in ADHD, with the most pronounced delay occurring in the prefrontal cortex.[32] Cortical thickness is also reduced in children with ADHD relative to controls, but when adults with ADHD remit, their cortical thickness is not different from controls.[33] There is evidence that the continued use of stimulants for the treatment of ADHD is associated with greater normalization of cortical thickness.[34] Reduced cerebellar volume is the most pronounced difference in ADHD versus controls.[35] The ENIGMA ADHD study obtained structural

MRI in 1,713 individuals with ADHD and 1,529 controls, both children and adults.[36] Subcortical structures (accumbens, amygdala, caudate, hippocampus, and putamen) were reduced in those with ADHD relative to controls, with effect sizes of around 0.2. Effects were larger in children than adults. In totality, the structural imaging data suggest ADHD is caused by a wide scale process affecting many regions of the brain.

② Functional MRI has shown that the brains of children with ADHD fail to activate a network of regions involved in attention and impulse control relative to controls.[37] During inhibitory tasks, children with ADHD fail to activate the right inferior frontal cortex and anterior cingulate cortex. When performing attention tasks, children with ADHD have reduced activation in the basal ganglia, prefrontal cortex, and parietal lobe, while they have increased activation of cuneus. There is increasing interest in the role of the default mode network (DMN) in many psychiatric disorders.[38] The DMN consists of the medial prefrontal cortex, medial parietal lobe, or precuneus, as well as the posterior cingulate. These areas are active during the “resting state” when attention is not engaged; this system is actively suppressed during active attention. A lack of connectivity between the prefrontal cortex and precuneus is associated with failure of suppression of the DMN, causing lapses in attention and inhibitory control. Multiple studies have shown that both children and adults diagnosed with ADHD, DMN activity is not appropriately connected to the attention/control areas compared to controls.[38–40] Treatment with stimulants normalizes DMN activity.[39] Functional MRI can be used to assess general connectivity between a large number of brain regions. A major review showed that children with ADHD have stronger short-range connections (particularly with limbic areas) than controls, but reduced number of long-range connections in the attention and control systems of the brain.[41]

Overall, ADHD is a complex neurodevelopmental disorder involving an array of genetic and environmental risk factors, many of which are shared with other psychiatric disorders. Clinicians can help families to better understand ADHD and minimize its negative impact on outcomes. More background information regarding pharmacogenomics can be found in Chapter e6, “Pharmacogenetics.”

CLINICAL PRESENTATION

③ TheAAP guideline for the diagnosis, evaluation, and treatment of ADHD in children and adolescents recommends an evaluation for any child between ages 4 and 18 years who presents with academic or behavioral problems and symptoms of inattention, hyperactivity, or impulsivity.[3] The *DSM-5* diagnosis in children 4 to 12 years old only requires at least six symptoms of inattention or hyperactivity and impulsivity causing impairment in more than one major setting (eg, home, school) for 6 months and an onset of symptoms before age 12. Only five symptoms are required for older adolescents and adults (age 17 and over).[1] Validated rating scales, such as the Connors Rating Scales—revised (CRS-revised) and the Vanderbilt ADHD diagnostic scale, are recommended for objective symptom ratings from parents and teachers in different age groups (See Chapter e81 for more information.)[3–5] To make a diagnosis of ADHD, the clinician should rule out alternative causes of symptoms (eg, learning disability, situational stressor) and assess for other conditions that may coexist with ADHD including oppositional defiant and conduct disorders (CDs), Tourette disorder, ASD, sleep and mood disorders.[1,3–5,42]

Preschoolers (3 to 5 Years)

Preschool-age onset of ADHD may be more likely in children with multiple risk factors including maternal smoking, lead exposure, iron deficiency, developmental delay, ASD, intellectual disability, or genetic loading.[43,44] The *DSM-5* diagnostic criteria for ADHD can be applied to preschool-age children, although it may be difficult to document symptoms in multiple settings with different caregivers if the child does not attend preschool.[1,3,12,44] Enrollment in a qualified preschool and a parent training program is often recommended. Both can help parents develop reasonable expectations for their child’s development and foster the development of management skills for problem behaviors while diagnostic assessment is underway.

School Age (6 to 11 Years)

Most cases of ADHD are first realized during ages 6 to 9 years, with the child having difficulty academically and/or socially in school and at home. Most children have combined inattentive and hyperactive or impulsive symptoms that cause functional impairment. This period is crucial to the child’s success in school, socialization, and the development of his or her sense of self; therefore, accurate diagnosis and treatment are critical. Comorbid oppositional defiant disorder (ODD), CD, and aggression are indicators that the child is at greater risk for issues with the criminal legal system and an SUD in adolescence.[8,10,45] This is the most well-studied age group, with strong data showing benefits of recognition and treatment with behavioral interventions and medications.[4,5]

Adolescents (12 to 18 Years)

Hyperactivity decreases in adolescents, and inattention and impulsivity are the more prominent.. There may be fewer numbers of symptoms of ADHD in adolescence, but the symptoms present cause significant functional impairment.[1,8,10] Adolescents with ADHD are increasingly identified as “moody” or having a temper. They are easily overwhelmed by demands and may avoid tasks or approach multiple tasks in a disorganized manner.[8] Decision making is impaired (eg, discontinues ADHD treatment despite functional impairment) and decisions are made based on peer approval.[8] Higher rates of delinquency, substance and alcohol use, and psychiatric comorbidity have been documented in adolescents with ADHD compared with those without ADHD.[3,4,10,11,46] Assessment for substance use and risk of diversion must be considered before starting stimulant medication.[8,46] Speeding and increased motor vehicle accidents occur at higher rates in teens with ADHD compared to those without the disorder.[8,47]

Adults

The presence of multiple comorbid conditions, particularly CD or mood disorder, can increase the likelihood of ADHD chronicity into adulthood. *DSM-5* criteria for ADHD in childhood and adolescence also apply to adults. Inattentive symptoms are the most common and functionally impairing in adults, but hyperactive/restless and impulsive symptoms such as being overly talkative, impatient, and intrusive are experienced by many and are associated with higher rates of bipolar disorder and psychosis.[1,2,10,11,48] Cognitive deficits (eg, executive functioning, working memory, task prioritization, lower IQ) have been documented in adults with ADHD in addition to a greater risk for unstable relationships, unemployment, psychiatric hospitalization, and interaction with the criminal legal system compared with those without ADHD.[2,10,11,48] In 2017, the World Health Organization published a six-item questionnaire to update the Adult ADHD Self-Report Scale (ASRS) with *DSM-5* diagnostic criteria. This validated screening tool can be used as a first step to a more thorough diagnosis with an experienced clinician.[2,49] Gathering collateral information from family and friends is recommended to either support or refute the diagnosis.

Adult-Onset ADHD

Adult-onset ADHD is increasingly recognized although still controversial. A Brazilian study evaluated 5,249 youth in 1993 at age 11 and found 393 (8.9%) met criteria for ADHD. Evaluation of the group in 2015 at age 18 to 19 years revealed 492 (12.2%) youth who had no symptoms in childhood, now meeting criteria for ADHD.[50] Interestingly, the childhood-onset group was predominantly male and the young adult-onset group was predominantly female. Both groups had increased levels of impairment (eg, comorbidities, involved with the criminal justice system, suicide attempts) compared to those without ADHD. United Kingdom investigators studied 2,040 twins longitudinally between 1994 and 2015. In adulthood, 166 met criteria for ADHD and 111 of whom (67%) had no symptoms during childhood.[51] Adult-onset ADHD raises many questions about potential causes (eg, cannabis use, alcohol use, chronic anxiety), diagnostic categorization, and treatment. Is young adult-onset ADHD a different brain disorder with similar symptoms to childhood-onset ADHD; is the course different? More research is needed.

Complex ADHD

A person is said to have “Complex ADHD” when there is moderate-to-severe functional impairment, diagnostic uncertainty, coexisting conditions (eg, neurodevelopmental, mental health, medical, or psychosocial factors adversely affecting health and development), inadequate response to treatment or when functionally impairing symptoms present before age 4, or after age 12. The Society for Developmental and Behavioral Pediatrics developed this designation to encourage expert evaluation and treatment of these individuals beyond usual care.[52]

Clinical Presentation: ADHD

General

- Onset of symptoms must be before 12 years of age.

Symptoms

- *Inattention:*
    - Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (eg, overlooks or misses details, or work is inaccurate)
    - Often has difficulty sustaining attention in play activities or tasks (eg, has difficulty remaining focused during lectures, conversations, or lengthy reading)
    - Often has difficulty organizing tasks and activities (eg, poor time management, disorganized work, fails to meet deadlines)
    - Avoids tasks that require sustained mental effort (eg, schoolwork, reviewing lengthy papers, or preparing reports)
    - Often does not seem to listen when spoken to directly (eg, mind seems to wander)
    - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace
    - Is easily distracted by extraneous stimuli (may include unrelated thoughts)
    - Is often forgetful in daily activities (eg, doing chores, returning calls, paying bills)
    - Loses things necessary for activities (eg, school materials, keys, wallet)
- *Hyperactivity and impulsivity:*
    - Often fidgets with hands or feet or squirms in seat
    - Often leaves seat when remaining seated is expected
    - Often runs about or climbs excessively at inappropriate times (in adolescents or adults may be limited to feeling restless)
    - Often has difficulty playing quietly
    - Often blurts out answers before a question is completed (also finishes the sentences of others; cannot wait for turn in conversation)
    - Often interrupts or intrudes on others; may take over what others are doing
- Six or more symptoms must be present for at least 6 months; significant impairment must be seen in two or more settings (eg, home and school); symptoms must be documented by parent, teacher, and clinician. Only five symptoms are required in older adolescents and adults (17 years of age and older).

Data from Reference 166.

TREATMENT

Stimulants are considered first-line therapy in most cases of ADHD; however, age, comorbid conditions, and patient/family preference impact treatment plan development. Pharmacotherapy should be considered whenever a thorough diagnostic assessment results in an ADHD diagnosis. ADHD-specific educational, cognitive, and behavioral interventions are recognized as necessary components of an overall treatment plan aimed at symptom relief and optimal functioning. Several studies show combining medications with behavioral interventions produces the greatest symptom relief and the best outcomes.[2,3,4,17,53]

Desired Outcomes

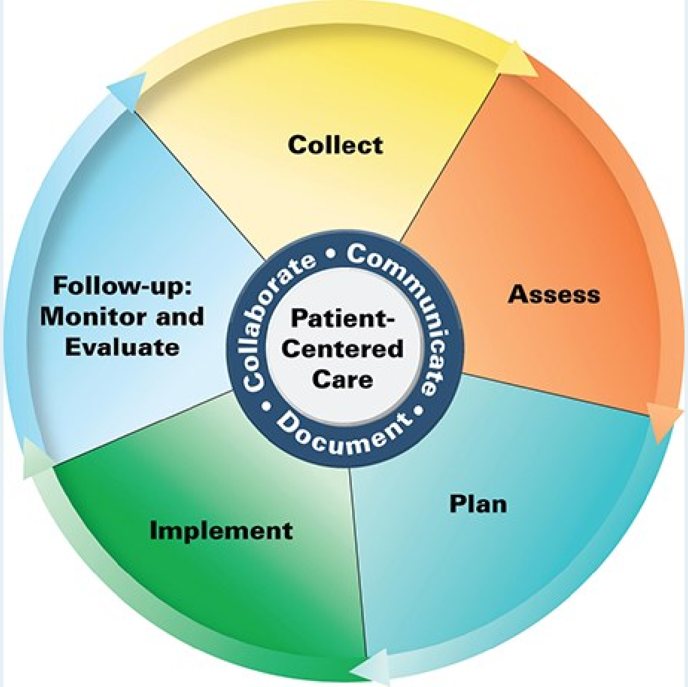
4 Specific goals of treatment or desired outcomes must be identified (eg, able to sit in chair for 20 minutes, completes homework assignments, or no longer blurts out comments in class without being called upon).[3,42] For adults, the desired outcome may be to read an entire newspaper before starting another project, improving safety while driving or successfully completing tasks on time at school or at work.[2,8,48]

Treatment for ADHD may decrease the rate of some serious injuries in youth. Investigators evaluated a large German healthcare database (reflecting 20% of the population) and found that in children with ADHD aged 3 to 17 years, treated with a stimulant or atomoxetine, there was no difference in overall injury rates requiring hospital admission compared to untreated children; however, there was a 34% decrease in severe brain injury in the treated group.[54] Similarly, an international review and meta-analysis of about 13,000 youth found that pharmacologic treatment in pediatric patients with ADHD likely has a protective effect, with a 10% reduction in the incidence of any unintentional injury. Of note, traumatic brain injury was excluded as an endpoint, given the potential to increase a patient's likelihood for being diagnosed with ADHD.[55]

Improvement in academic performance and on-task behavior in the classroom has been associated with stimulant treatment of ADHD.[56] A study of 930 young adults with ADHD found that treatment with pharmacotherapy (eg, stimulants and atomoxetine) was associated with significantly improved scores on higher education entrance exams compared to never-medicated peers.[57] Review of the Icelandic Medicines Registry and the Database of National Scholastic Examinations revealed that delayed initiation of pharmacologic treatment may be associated with academic decline among youth age 9 to 12 years, particularly in math.[58] Additionally, other studies have demonstrated improvement in math productivity, accuracy, and reading speed with methylphenidate treatment, although academic improvements were thought to be small compared to overall symptom improvement.[59]

PATIENT CARE PROCESS

Patient Care Process for Attention Deficit/Hyperactivity Disorder (ADHD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, gender, sex, pregnancy status)
- Social and family history (eg, foster care, single parent home, extended family involvement; marital status for adults)
- Substance use history (eg, cigarettes, cannabis, alcohol, methamphetamine, hallucinogens, cocaine, opioids, kratom, salvia)
- Dietary issues (eg, "picky" eater, gluten-sensitive, food allergies)
- Sleep patterns (eg, latency, duration, restless legs)
- Current medications including OTCs, herbal products, dietary supplements, and prior medications for ADHD
- Cardiovascular health history (eg, history of sudden death in family)
- Goals of treatment (eg, finish homework assignments or work projects, prevent injury, await turn in lines, positive peer/family interactions)
- Information on past and current co-occurring neuropsychiatric conditions (eg, Tourette disorder, CD, bipolar disorder, ASD, epilepsy)
- Objective data
    - Measure symptoms of ADHD with validated rating scales for children or adolescents (eg, Conners, Vanderbilt) and ADHD self-rating questionnaire for adults
    - Gather information on symptoms in multiple settings (eg, school, work, home)
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, body mass index (BMI), growth chart data on percentiles based on general pediatric population
    - Labs including liver function tests (LFTs), electrolytes, renal function, fasting lipid panel, and HgA1c, thyroid tests if co-occurring anxiety or mood symptoms, ECG and/or echocardiogram if history reveals significant cardiovascular disease or sudden unexplained death in family member, and pregnancy status in females

Assess

- Number and predominance of symptoms (eg, are inattentive symptoms the only significant symptom?)
- Severity of symptoms (eg, hyperactivity, impulsivity, and inattention) and associated functional impairment
- Presence and severity of co-occurring conditions (eg, Tourette disorder, CD, bipolar disorder, ASD)
- Presence of active SUD in patient and family members
- Presence of adverse reactions from current medications (Tables 80-3 and 80-4)
- Ability/willingness to participate in nonpharmacologic treatment including psychosocial, cognitive, and behavioral interventions
- Identify barriers to adherence to pharmacotherapeutic interventions and participation in ongoing treatment (eg, cost, frequency of medication administration throughout the day, transportation challenges to follow-up appointments)

Plan*

- Medication therapy regimen including specific medication(s), dose, route, frequency, and duration (Tables 80-2 through 80-4 and Fig. 82-1)
- Monitoring parameters including efficacy (eg, decreased symptoms on rating scales) and safety (eg, heart rate, blood pressure, abnormal involuntary movements); frequency and timing of follow-up (Tables 80-3 and 80-4)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, medication-specific information, medication administration)

- Referrals to other providers when appropriate (eg, pediatrician, dietician)

Implement[*]

- Provide patient, parent, caregiver(s), teacher, partner education regarding all elements of treatment plan; education should be delivered in multiple forms (Table 82-1)
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up appointment for monitoring and pharmacotherapy dosage adjustment (Tables 80-1 through 80-3)

Follow-up: Monitor and Evaluate

- Significant improvement in ADHD symptoms (eg, inattention, hyperactivity, impulsivity)
- Presence of adverse effects (eg, insomnia/sedation, appetite change, increased or decreased HR)
- Presence of significant medication interactions (eg, fluoxetine and atomoxetine, or paroxetine and amphetamine salts)
- Patient adherence to treatment plan using multiple sources of information
- Re-evaluate dosage and tolerability every 1 to 3 months

[*] *Collaborate with patient, caregiver(s), and other healthcare professionals.*

Nonpharmacologic Therapy

Educational, Psychosocial, Cognitive, and Behavioral Interventions

⑤ Education that ADHD is a biologic disorder with brain-derived causes is essential for destigmatizing ADHD and improving treatment acceptance. Parent training and behavioral interventions such as positive rewards for good behavior and structured limit setting are recommended as first-line interventions before medication trials in preschoolers (3- to 5-year-olds) with ADHD. Behavioral interventions for ADHD are described in Table 82-1. It is crucial to get parents, teachers, and clinicians involved to coordinate care and provide consistent behavioral management for the child at home and at school. Although methylphenidate has been found safe and effective for ADHD in 4- and 5-year-olds, behavioral interventions are recommended first by most clinicians and guidelines.[3,60] School-age children (6-11 years) also benefit from these behavioral interventions in addition to strategies, such as breaking up homework assignments into shorter, manageable segments. Although it varies by state, children and adolescents with ADHD may qualify for an individualized educational program (IEP) that allows for more time to take an exam, preferred seating, and modified work assignments.[3,4,45] It is noteworthy that most studies comparing behavioral intervention with stimulant therapy in youth found a much stronger effect on ADHD core symptoms from stimulants.[4,5,7,61] Combined behavioral and stimulant therapy resulted in greater improvements on academic and conduct measures in some studies with greater parent and teacher satisfaction ratings. Lower doses of stimulant were effective when behavioral interventions were administered according to several studies.[4,62]

TABLE 82-1

Cognitive, Behavioral, and Psychosocial Interventions for ADHD

Age	Description of Intervention	Typical Outcomes
Preschool and school age	Parent and family education on ADHD	Improved parental understanding and satisfaction
	Parent/caregiver training on behavioral management	Improved compliance with parental commands
	Classroom management instruction for teachers	Improved teacher satisfaction
Adolescent	Breakup homework assignments into manageable segments. Structured schedule; organizer	Completion of assignments improves; improved self-esteem and sense of self
Adolescent and adult	ADHD-specific cognitive behavioral therapy	Improved productivity and vocational success
	Metacognitive therapy	Improved relationships

ADHD, attention deficit/hyperactivity disorder.

Data from References [3,5,42,53,60,61,63]

5 Recommended behavioral interventions for adolescents and adults include keeping an external organizer (eg, smart phone, notebook with "to-do" lists) and breaking up activities into short, manageable tasks. Recognizing triggers for distraction and making a point of thinking before acting are useful interventions and are recommended during cognitive behavioral therapy (CBT) sessions designed to manage adult ADHD.[53,63] Controlled studies have shown that ADHD-specific CBT was more effective than psychoeducation and relaxation in adults with ADHD whose symptoms were only partially responsive to medication.[63] One study in 88 adults compared 12 weekly sessions (1.5 hour long) of manualized CBT administered with a long-acting formulation of methylphenidate or amphetamine salts to CBT alone and found greater benefit in ADHD symptoms, organizational skills, and self-esteem in the combination CBT and medication group at the end of 12 weeks. Of note, the CBT alone group continued to improve according to unblinded clinician assessment and self-report after 6 months of treatment.[53] Yoga, meditation, and some dietary supplements have been recommended for ADHD as well, but they should not take the place of more established effective treatments, such as medications and cognitive interventions.[61,64] External trigeminal nerve stimulation (eTNS) is FDA approved for pediatric patients with ADHD; however it is not recommended by the AAP guidelines given lack of long-term safety and efficacy data.[3]

Dietary Interventions

Extensive research has evaluated dietary interventions for ADHD, primarily in children with some adolescent data. Omega-3 fatty acids are the most studied dietary intervention for ADHD. While studies have demonstrated variable impact on core ADHD symptoms, omega-3 supplementation is generally well tolerated and has demonstrated and effect size of approximately 0.3.[65] High eicosapentaenoic acid (EPA) to docosahexaenoic acid (DHA) ration may be associated with the largest effect.[65]

When iron and zinc are supplemented in youth with known deficiencies, the therapeutic benefit of stimulant therapy can be enhanced, frequently allowing lower effective doses.[66–68] Vitamin D may also improve symptoms of ADHD, particularly in youth with deficiencies according to a randomized double-blind trial in 96 children of mean age 9 years old.[69]

The role of gingko biloba, Memoemet syrup, and other complementary and alternative products has also been evaluated, with variable efficacy and tolerability.[5] While some evidence is promising, ongoing evaluations are needed before recommending these products, given variability in study design (eg, use of concomitant pharmacotherapy, rating scales to assess symptom improvement, and variability among products used). While it has been anecdotally suggested that cannabidiol oil is beneficial for ADHD, it has not been rigorously studied for core symptoms and is not recommended.[3]

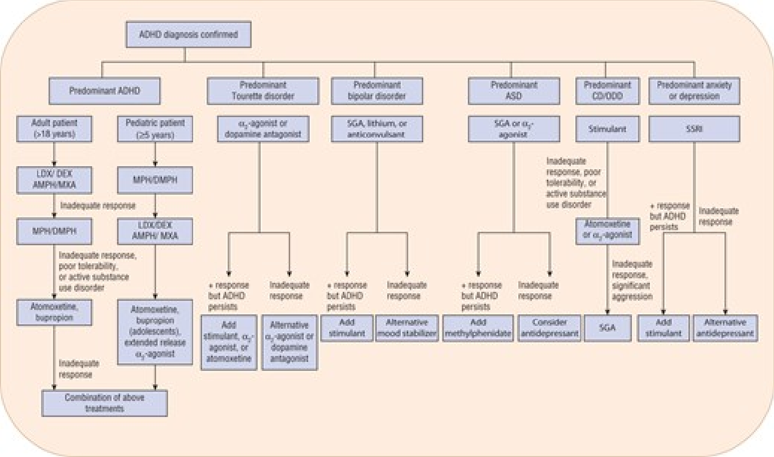
Although scientific evidence is lacking, there is a universal belief among families that the avoidance of sugar and artificial sweeteners improves ADHD symptoms. The attention paid to sugar avoidance and healthy diet is the more likely reason for improved behavior. An overall healthy diet with the proper balance of protein, fresh produce, and fiber is recommended.[12,17,61,66]

Pharmacologic Therapy

Figure 82-1 is an algorithm for medication selection in the treatment of ADHD.

FIGURE 82-1

Algorithm for medication selection in the management of attention deficit/hyperactivity disorder (ADHD). Treat predominant disorder first, reassess, and consider alternative or adjunct medications for optimal symptom control. (AMPH, amphetamine; DEX, dextroamphetamine; DMPH, dexmethylphenidate; LDX, lisdexamfetamine; MPH, methylphenidate; MXA, mixed amphetamine salts; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant). *(Data from References [2, 5, 45, 60,70–77].)*



ADHD diagnosis confirmed
Predominant ADHD
Predominant Tourette disorder
Predominant bipolar disorder
Predominant ASD
Predominant CD/ODD
Predominant anxiety or depression
Adult patient (>18 years)
Pediatric patient (≥5 years)
α2-agonist or dopamine antagonist
SGA, lithium, or anticonvulsant
SGA or α2-agonist
Stimulant
SSRI
LDX/ DEX AMPH/MXA
MPH/DMPH
Inadequate response
MPH/DMPH
LDX/DEX AMPH/ MXA
Inadequate response, poor tolerability, or active substance use disorder
Inadequate response, poor tolerability, or active substance use disorder
Atomoxetine or α2-agonist
+ response but ADHD persists
Inadequate response
Atomoxetine, bupropion
Atomoxetine, bupropion (adolescents), extended release α2-agonist
+ response but ADHD persists
Inadequate response
+ response but ADHD persists
Inadequate response
+ response but ADHD persists
Inadequate response
Inadequate response, significant aggression
Add stimulant, α2-agonist, or atomoxetine
Alternative α2-agonist or dopamine antagonist
Add stimulant
Alternative mood stabilizer
Add methylphenidate
Consider antidepressant
SGA
Add stimulant
Alternative antidepressant
Inadequate response
Combination of above treatments

lisdexamfetamine (LDX)/dextroamphetamine (DEX) or amphetamine (AMPH)/mixed amphetamine salts (MXA). If there is inadequate response, try methylphenidate (MPH)/dexmethylphenidate (DMPH). If there is inadequate response, poor tolerability, or active substance use disorder, give atomoxetine or bupropion. If there is inadequate response, try combination of above treatments. In pediatric patients (≥5 years) with predominant ADHD, start treatment with MPH/DMPH. If there is inadequate response, try LDX/DEX or AMPH/MXA. If there is inadequate response, poor tolerability, or active substance use disorder, give atomoxetine or bupropion (adolescents), extended release alpha 2-agonist. If there is inadequate response, try combination of above treatments. If the patient has predominant Tourette Disorder, start treatment with alpha 2-agonist or dopamine antagonist. If there is positive response but ADHD persists, add stimulant, alpha 2-agonist, or atomoxetine. If there is inadequate response, try alternative alpha 2-agonist or dopamine antagonist. If the patient has predominant bipolar disorder, start treatment with second-generation antipsychotic (SGA), lithium, or anticonvulsant. If there is positive response but ADHD persists, add stimulant. If there is inadequate response, try alternative mood stabilizer. If the patient has predominant autism spectrum disorder (ASD), start treatment with SGA or alpha 2-agonist. If there is positive response but ADHD persists, add methylphenidate. If there is inadequate response, consider antidepressant. If the patient has predominant conduct disorder (CD)/oppositional defiant disorder (ODD), start a stimulant. If there is inadequate response, poor tolerability, or active substance use disorder, start atomoxetine or alpha 2-agonist. If there is inadequate response or significant aggression, give SGA. If patient has predominant anxiety or depression start selective serotonin reuptake inhibitor (SSRI). If there is positive response but ADHD persists, add stimulant. If there is inadequate response, add antidepressant." class="contentFigures" />

Several studies demonstrate the superiority of stimulants over other pharmacotherapies and behavioral interventions in alleviating core symptoms of ADHD in schoolage children, adolescents, and adults.[5,17,60] Although the United Kingdom's 2018 National Institute for Health and Care Excellence (NICE) guidelines recommend considering medication as early as 5 years of age, the clinician needs to weigh the risks of starting medication at an early age against the harm of delaying diagnosis and treatment.[3,4,42,44] Clinicians should educate all parents and caregivers regarding realistic expectations of medication therapy, goals of treatment, and the need for adverse effect monitoring in children. Adolescents and adults should be actively engaged in shared decision-making regarding medication therapy and monitoring in an attempt to improve treatment persistence. Studies show higher rates of medication non-adherence in adolescents (50%) and adults (30%) compared to children (10–30%).[8] Preventing misuse and diversion of stimulants through frequent communication with patients and family, the use of a controlled substance agreement, and by tracking state-wide prescription medication monitoring databases is recommended.[2]

Stimulants

Stimulants are broadly divided into two main chemical classes: methylphenidate (includes dexmethylphenidate) and amphetamines (includes dextroamphetamine and mixed amphetamine salts). Methylphenidate and amphetamines block presynaptic dopamine and norepinephrine reuptake; amphetamines also increase dopamine release.[7,78] Both medications inhibit monoamine oxidase (MAO), amphetamines more potently than methylphenidate.[78] Because different stimulants work through slightly different mechanisms, the lack of response to one chemical class of stimulant (eg, methylphenidate or dexmethylphenidate) does not preclude response to another class (eg, mixed amphetamine salts, dextroamphetamine, or lisdexamfetamine).[7]

⑥ Stimulants are the most effective medication treatment options, with a pooled average effect size of 0.7 to 1.0. This is in contrast to nonstimulant medication treatment options such as guanfacine, clonidine, and atomoxetine whose effect sizes range from 0.35 to 0.7 signifying lower efficacy.[4,71,74] A systematic review and meta-analysis of 133 double-blind randomized controlled trials (81 in children and adolescents [*n* = 11,018], 51 in adults [*n* = 5,362], 1 in both) was conducted to assess the efficacy and tolerability of ADHD pharmacotherapy over 12 weeks in different age groups. Overall, the analysis showed stimulants were more effective than nonstimulant medications in all ages; however, stimulants were not as effective in adults compared to children and adolescents.[71]

Among children and adolescents, all approved ADHD medications were superior to placebo (clinician report), with amphetamines superior to methylphenidate, modafinil, atomoxetine, and guanfacine. Methylphenidate was superior to atomoxetine. Per teacher report, only methylphenidate and modafinil were superior to placebo. Guanfacine and amphetamines were less well tolerated than placebo, with amphetamines demonstrating a significant increase in systolic blood pressure and weight loss among children and adolescents, more than methylphenidate.

Because the largest analysis of clinical trial data showed overall better tolerability with methylphenidate in children and adolescents compared to amphetamine compounds, many clinicians recommend methylphenidate first-line in younger age groups. Nonetheless, amphetamine may be used first-line if patient and clinician prefer it.

In contrast to recommendations for pediatric patients, an amphetamine compound is preferred over methylphenidate as a first-line medication for adults based on the analysis of 12-week trials showing greater efficacy and acceptable tolerability of amphetamine compounds in adults versus pediatric patients.[71] In adults, amphetamines, methylphenidate, bupropion, and atomoxetine were superior to both placebo and modafinil. Modafinil did not demonstrate superiority in adults. With the exception of bupropion, all agents in adults were less well tolerated than placebo.[71][

Stimulant dosing should be titrated for maximum individual efficacy and minimum adverse medication reactions[4,5,7,42] (Table 82-2).

TABLE 82-2

Dosing of Stimulant medications Used in the Treatment of ADHD

Stimulant	Duration of Effect	Initial Dose and Available Strengths	Usual Dosing Range; Maximum Dose
Methylphenidate C-II[a]			
Short-acting IR			
Ritalin, methylin, generics[b]	3-5 hours	5 mg two or three times daily; increase by 5-10 or 20 mg/day at weekly intervals; available as 5, 10, and 20 mg tablets; 5 mg/mL and 10 mg/5mL solution	5-20 mg two or three times daily; Max: 60 mg/day
Dexmethylphenidate (Focalin) C-II	3-5 hours	2.5 mg every AM or twice daily; available as 2.5, 5, and 10 mg tablets	2.5-10 mg twice daily; Max: 20 mg/day

Intermediate-acting			
Ritalin SR[b]	3-8 hours	20 mg every AM; increase at weekly intervals; available only as 20 mg tablets	20-40 mg every AM or 40 mg every AM and 20 mg in the early afternoon; Max: 60 mg/day
Methylphenidate SR[b]			
Metadate ER[b]			
Methylin ER[b]			
Long-acting			
Ritalin LA 50% IR, 50% ER beads[b]	8-10 hours	20 mg every AM; available as 10, 20, and 30 mg	20-60 mg every AM; Max: 60 mg/day
Metadate CD 30% IR, 70% ER beads[b]	10-12 hours	20 mg every AM; available as 20, 30, and 40 mg	
Concerta (OROS controlled-release delivery)[b]*ER inner compartments coated with IR methylphenidate*	10-12 hours	18 mg every AM; available as 18, 27, 36, and 54 mg; 90% bioavailability of IR	27-72 mg every AM; Max: 72 mg/day
Daytrana methylphenidate transdermal system[b]	12 hours when worn for 9 hours	10 mg (12.5 cm^2) applied to clean, dry area on hip each morning and removed after 9 hours; available as 10, 15, 20, and 30 mg patches	10-30 mg (12.5-37.5 cm^2). Medication active for 3 hours after patch removal
Aptensio XR 40% IR, 60% ER	10-12 hours	10 mg; available as 10, 20, 30, 40, 50, and 60 mg capsules	10-60 mg every AM; Max: 60 mg/day
Cotempla XR-ODT 25% IR, 75% ER[b]	10-12 hours	17.3 mg every AM; available as 8.6, 17.3, 25.9 mg oral disintegrating tablets	17.3-51.8 mg every AM; Max: 51.8 mg/day
Quillivant extended-release suspension 20% IR/80% ER[b] *Must be reconstituted by pharmacist to 25 mg/5 mL concentration. Stable for 4 months after reconstituted*	10-12 hours	10-20 mg in AM; available as 25 mg/5mL suspension*Only studied in 6- to 12-year-olds*	20-60 mg every AM; Max: 60 mg/day
QuilliChew ER 30% IR, 70% ER	10-12 hours	10-20 mg in AM; available as 20, 30, and 40 mg tablets	
Jornay PM[b] delayed-release, extended-release formulation*(administer at bedtime)*		20 mg in PM; available as 20, 40, 60, 80, and 100 mg capsules	20 mg every evening between 7 and 9 PM; Max: 100 mg/day
Adhansia XR 20%IR, 80% ER	12-16 hours	25 mg every AM; available as 25, 35, 45, 55, 70, and 85 mg capsules	25-85 mg every AM; Max: 70 (child) 85 (adult) mg/day

Focalin (dexmethylphenidate) XR 50% IR, 50% ER beads[b]	10-12 hours	5 mg every AM; available as 5, 10, 15, 25, 30, 35, and 40 mg capsules	5-40 mg every AM; Max: 30 mg/day (children and adolescents); Max 40 mg/day (adults)
Serdexmethylphenidate (SDX)/dexmethylphenidate (Azstarys) 70% SDX, 30% IR dMPH	10-12 hours	39.2/7.8 mg every AM; available as 26.1/5.2, 39.2/7.8, 52.3/10.4 mg capsules (SDX/dMTP)	26.1/5.2–52.3/10.4 mg every AM; Max 52.3/10.4 mg/day
Mixed Amphetamine Salts C-II			
Short-acting IR			
Adderall, mixed amphetamine generics[c] *(dextroamphetamine and levoamphetamine 3:1 ratio)*	4-6 hours	2.5-5 mg every AM to twice daily; available as 5, 10, 7.5, 12.5, 15, 20, 30 mg tablets	5-40 mg every AM or divided 2.5-20 mg twice daily; Max: 40 mg/day
Amphetamine C-II (dextroamphetamine and levoamphetamine ratio 1:1)[c](Evekeo)	4-6 hours	2.5-5 mg every AM to twice daily; available as 5 and 10 mg tablets	5-40 mg every AM or divided 2.5-20 mg twice daily; Max: 40 mg/day
Long-acting			
Long-acting XR (Adzenys XR-ODT) dextroamphetamine and levoamphetamine ratio 3:1[d]3.1 mg Adzenys ODT ~ 5 mg of Adderall XR	10-12 hours	3.1-9.4 mg every AM; available as 3.1, 6.3, 9.4, 12.5, 15.7, 18.8, extended-release oral disintegrating tablets	3.1-18.8 mg every AM; Max: 18.8 mg/day
Mydayis (triple-bead formulation of mixed amphetamine salts)[e]	12-16 hours	12.5-25 mg every AM; available as 12.5, 25, 37.5, 50, extended-release capsules	12.5-50 mg every AM; Max: 50 mg/day (adults), 25 mg/day (pediatrics)
Adzenys ER-oral suspension[d]	10-12 hours	1.25 mg/mL oral suspension	6.3-18.8 mg every AM; Max: 18.8 mg/day
Dyanavel XR 2.5 mg/mLDextroamphetamine and levoamphetamine ratio 3.2:1[d]	10-12 hours	2.5 mg/1 mL oral suspension2.5 mg of suspension ~ 4 mg of mixed amphetamine salts	5-20 mg every AM; Max: 20 mg/day
Mixed amphetamine salts C-IIExtended-release capsule (Adderall XR) dextroamphetamine and levoamphetamine ratio 3:1[d]	10-12 hours	5-10 mg every am; available as 5, 10, 20, 30 mg extended-release capsule	5-30 mg every AM; Max: 30 mg/day
Dextroamphetamine C-II			
Short-acting			
Dextroamphetamine generics[c]	3-5 hours	2.5 mg every AM to two or three times daily; available as 2.5, 5, 7.5, 10, 15, 20, and 30 mg tablets and 5 mg/5 mL solution	5-20 mg twice daily; Max: 40 mg/day
Dexedrine, Zenzedi[c]			
Intermediate-acting			

Dexedrine Spansule[d]	5-8 hours	5 mg every AM; available as 5 and 10 mg	5-30 mg every AM or 5-15 mg twice daily; maximum: 40 mg/day
Long-acting			
Lisdexamfetamine (Vyvanse)[d](prodrug converted to dextroamphetamine)	10-12 hours	30 mg every AM; Available as 20, 30, 40, 50, 60 capsules and chewable tablets and 70 mc capsules	Start at low end; titrate weekly to response; give in AMSlower onset compared with other dextroamphetamine products

ER, extended release; IR, immediate release; OROS, osmotically released oral delivery system; ODT, orally disintegrating tablet; SR, sustained release; XR, extended release.

[a] The Drug Enforcement Administration label C-II, schedule II refers to significant abuse potential.

[b] Methylphenidate and dexmethylphenidate products are FDA approved in ≥6 years old.

[c] Immediate-release amphetamine and dextroamphetamine products are FDA approved in ≥3 years old.

[d] Extended-release amphetamine and dextroamphetamine products are FDA approved in ≥6 years old.

[e] Extended-release amphetamine product (immediate-release bead, small intestine dissolution bead, large intestine dissolution bead) FDA approved in ≥13 years old.

Data from References 74,79–81 and stimulant product package inserts or Daily Med.

Stimulants are available in diverse formulations (immediate release, delayed release, extended release, liquids, orally disintegrating tablets [ODTs] and patches) to allow for individualization based on a child's ability to swallow solid formulations and to individualize the duration of symptom control. Once-daily stimulant formulations are the preferred treatment for ADHD in most individuals due to convenience and better medication adherence.[5,74,81] Immediate-release formulations have the advantage of lower cost, less insomnia, and potentially fewer growth effects versus extended-release products; however, they also carry a higher risk of diversion and abuse.[2,45,74]

Administration of stimulant medications with food can delay the absorption and subsequently delay the onset of therapeutic effect by 30 minutes to 1 hour for immediate-release preparations and 1 to 2 hours for extended-release preparations.[74,81] Total bioavailability of stimulant can be decreased by 10% to 30% with coadministration of food, more so for beaded formulations of extended-release stimulant compared with osmotic-controlled release oral delivery system (OROS) methylphenidate or lisdexamfetamine.[17,74,81]

With immediate-release stimulants, most patients require a two or three times daily dosing schedule because of the short half-lives and duration of action of these medications (2-4 hours for methylphenidate and dexmethylphenidate and ~4 to 6 hours for dextroamphetamine or mixed amphetamine salts).[4,7] Medication response is maximal during the absorption phase, is evident in 15 to 30 minutes, and lasts 2 to 6 hours.[4,7]

Drug delivery systems of once-daily products (amphetamine aspartate, amphetamine sulfate, dextroamphetamine sulfate, and dextroamphetamine saccharate [Adderall XR]; methylphenidate [Concerta]; methylphenidate [Daytrana]; dexmethylphenidate [Focalin XR]; methylphenidate [Metadate CD]; and methylphenidate long-acting [Ritalin LA]) provide 8 to 12 hours of symptom control.[74,80] Concerta uses an oral OROS, whereas other oral preparations use combinations of immediate-release and extended-release beads.[74,80] Concerta is a nondeformable tablet, and it should not be given to children with gastrointestinal (GI) narrowing because of the risk of obstruction. Mydayis, a long-acting mixed amphetamine salt, provides up to 16 hours of symptom control in adolescents and adults via pH-dependent, triple bead technology.[79,82] Adhansia XR is an extended release methylphenidate capsule with a duration of action up to 16 hours.[80] A novel evening-dosed delayed-release/extended-release methylphenidate product (Jornay PM) has demonstrated improvement in early morning functional impairment among youth with ADHD. DELXIS technology utilizes a dual-layer (outer delayed-release, inner extended-release layer) microbead delivery system that surrounds an inner methylphenidate loaded core.[81,83,84]

Aztarys is a novel long-acting product composed of 30% immediate release dexmethylphenidate and 70% serdexmethylphenidate, a prodrug of dexmethylphenidate. A long-acting effect is produced through gradual bioactivation of serdexmethylphenidate to dexmethylphenidate in the lower GI tract.[85]

For patients with trouble swallowing pills, several alternative stimulant formulations are available. Methylphenidate transdermal system provides up to 12 hours of symptom control when worn for 9 hours.[74,80] Dyanavel XR, an extended-release amphetamine oral suspension, utilizes ion exchange chemistry (LiquiXR™ technology) to provide continuous release of amphetamine throughout the day.[86] Adzenys ER oral suspension (MXA) is a long-acting mixed amphetamine salt that has demonstrated efficacy in youth 6 to 17 years of age.[87] Cotempla XR-ODT (methylphenidate) and Adzenys XR-ODT MXA should also be considered for youth with trouble swallowing pills. Both products utilize micro-particle technology and have effects for 10 to 12 hours.[87,88] Lisdexamfetamine is a prodrug conjugated to an amino acid that requires cleavage during metabolism to the active dextroamphetamine. It has a longer time to onset of effect (~2 hours) but provides 10 to 12 hours of symptom control. As a prodrug, it has lower risk for misuse compared to other long-acting amphetamines where beads may be crushed or snorted. NICE guidelines recommend it as a preferred long-acting amphetamine formulation due to the extent of evidence for efficacy and safety in children, adolescents, and adults, and a lower misuse risk.[74,80]

Adverse Effects

The most common adverse effects of stimulants and their management strategies are listed in Table 82-3.[45,89] At least 15 cases of priapism (painful prolonged erection), associated with stimulant use, have been reported to the FDA in males with a mean age of 12.5 years. A few cases of priapism have been reported with atomoxetine, and all cases require immediate medical attention.[45,90] The FDA has received at least 51 reports of skin discoloration associated with the methylphenidate transdermal system, also known as chemical leukoderma, that may not be reversible.[74]

TABLE 82-3

Stimulant Adverse Medication Reactions and Their Management

Adverse Reaction	Recommendation/Management Strategy
Common	
Reduced appetite, weight loss	Give high-calorie meal when stimulant effects are low (at breakfast or at bedtime) or consider cyproheptadine at bedtime
Stomach ache	Administer stimulant on a full stomach; lower dose if possible
Insomnia	Give dose earlier in the day; lower the last dose of the day or give it earlier; consider a sedating medication at bedtime (guanfacine, clonidine, melatonin, or cyproheptadine)
Headache	Divide dose, give with food, or give an analgesic (eg, acetaminophen or ibuprofen)
Rebound symptoms	Consider longer-acting stimulant trial, atomoxetine, or antidepressant
Irritability/jitteriness	Assess for comorbid condition (eg, bipolar disorder); reduce dosage; consider mood stabilizer or second-generation antipsychotic
Uncommon to Rare	
Dysphoria	Reduce dosage; reassess diagnosis; consider alternative therapy
Skin discoloration (chemical leukoderma)	Counsel regarding risk before using methylphenidate patch
Zombie-like state	Reduce dosage or change stimulant medication
Tics or abnormal movements	Reduce dosage; consider alternative medication
Priapism (painful erection)	Obtain medical assistance immediately; consider alternative treatment
Hypertension, pulse fluctuations	Reduce dosage; change medication
Hallucinations	Discontinue stimulant; reassess diagnosis; mood stabilizer and/or antipsychotic may be needed
Peripheral vasculopathy, including Raynaud's phenomenon	Obtain medical assistance if severe digital changes observed; consider reducing dosage or alternative medication

Data from References [45, 60, 71, 74, and 89–92].

Psychiatric, cardiac, and growth effects of stimulants have been extensively studied with key data and recommendations in the sections below.

Psychiatric

Although considered rare, the FDA has added warnings to the labeling of all ADHD medications (ie, stimulants, atomoxetine, α_2-adrenergic agonists) regarding three broad categories of psychiatric adverse effects: psychosis, mood disturbance (ie, irritability, lability, or depression), and severe anxiety or panic attacks. Treatment-emergent psychosis is estimated to occur in approximately 1.5% of youth with ADHD treated with stimulant medications based on placebo-controlled trials.[45] Hallucinations involving visual or tactile sensations of insects, snakes, or worms were typical in children, with adolescents and adults experiencing hallucinations and delusions.[93] Multimodal Treatment Study of Children with ADHD (MTA), analyzing available data on the emergence of psychosis in 509 youth diagnosed with ADHD at age 7 to 9 years, showed that 5.1% reported psychosis which was not statistically different than 3.9% of the 276 local normal controls who reported psychosis over the same 10-year follow-up period. Therefore, investigators did not correlate stimulant use or an ADHD diagnosis in either group with the emergence of psychosis, but frequent cannabis use was associated with increased risk of psychosis in both groups.[94]

Sadness from stimulants may in part be genetically mediated, as an association was found in 77 youth taking immediate-release methylphenidate and two single nucleotide polymorphisms (SNPS) in the gene encoding for carboxylesterase (CES1), which may impact stimulant metabolism.[95] There is also evidence to suggest that preschool-aged youth are more susceptible to sadness, irritability, and mood lability with stimulant treatment compared with adolescents and adults[3,45,89]

Literature reviews describe treatment-emergent mania and psychosis with atomoxetine, primarily in those with underlying bipolar disorder or depression. Labeling for atomoxetine includes a warning of increased suicidality largely because of its mechanism of action that is similar to antidepressants. A worldwide analysis of clinical trial and post-marketing data show no increase in suicidality (hazard ratio of 0.96).[96] Both stimulants and atomoxetine/viloxazine have the potential to cause or exacerbate mania, anxiety, panic attacks, or depression. In addition, stimulants and atomoxetine should not be given to manage attention in individuals with a primary psychotic illness such as schizophrenia or schizoaffective disorder due to the high risk of worsening psychosis.[45,96] Clonidine and guanfacine are much less likely than stimulants or atomoxetine to cause psychosis, mania, or anxiety, but treatment-emergent psychosis, irritability, depression, and nightmares have been reported.[97] When psychiatric adverse effects occur, dose reduction or cessation of therapy and supportive treatment is recommended.[45]

Cardiac

Stimulants, atomoxetine, viloxazine, and α_2-adrenergic agonists have well-described cardiac and cardiovascular adverse reactions that are not significant for most youth, but can be intolerable in some, particularly in those with existing cardiac/cardiovascular disease.[45,98] Clinical trial data show that children who take stimulants for ADHD can have an increased heart rate by 3 to 10 beats/min and/or increased systolic or diastolic blood pressure by 2 to 14 mm Hg.[45,98] To explore the extent of cardiac adverse reactions more thoroughly, investigators used ECG and echocardiography to evaluate cardiac function in 58 children (ages 6-18 years old) with ADHD diagnosed, for at least 6 months, who were taking OROS methylphenidate (mean dose 39.40 mg or 0.93 mg/kg/day) and compared them to 58 matched control group children diagnosed with ADHD but not yet started on medication. Overall no significant differences were found in terms of blood pressure or ECG findings including QTc measurements; however, youth taking methylphenidate had lower E'septal values on echocardiography.[99] This difference was considered within normal limits and not indicative of cardiac dysfunction.

Clinical trial and post-marketing surveillance data shows atomoxetine treatment has been associated with increased heart rate at an average of approximately 5 beats/min and increased systolic or diastolic blood pressure of approximately 12 mm Hg. An Eli Lilly cardiovascular safety review showed 8% to 10% of patients taking atomoxetine had more significant increases in pulse at greater than or equal to 20 bpm and increase in systolic and/or diastolic blood pressure of greater than 15 to 20 mm Hg.[96] Clinical trial data demonstrate viloxazine treatment is associated with a greater than or equal to 20 beats/min increase in heart rate and greater than or equal to 15 mm Hg increase in diastolic blood pressure. Heart rate and blood pressure should be monitored prior to the initiation of treatment, following dose increases, and throughout treatment.[100] Clonidine and guanfacine may cause dose-related bradycardia and lowered blood pressure in youth, which may prevent upward titration in addition to modest widening of the QTc interval (5-7 msec) that warrants monitoring, particularly if the child takes another agent known to prolong QTc such as an antidepressant or antipsychotic.[45,97]

A 9.5-year prospective cohort study of children with ADHD found that, although rare, adverse cardiovascular events were twice as likely to occur in stimulant users as in nonusers.[101] There were 111 cardiovascular events in the 8,300 children with ADHD included in this analysis with hypertension, heart disease not otherwise specified, and cardiovascular disease not otherwise specified comprising 62% of adverse cardiac events, while arrhythmias comprised 23%, and cardiac arrest accounted for less than 1%.[45] The same investigators looked at national rates of stimulant use (*n* =

714,258) and found 1.8 times greater risk of cardiovascular events in those taking stimulants with greater risk seen with higher doses compared with lower doses.[101]

Overall, stimulant products should be used with caution in pediatrics and in adults with known structural cardiac abnormalities. The American Heart Association recommends careful screening of all children and adolescents prior to initiating pharmacologic therapy for ADHD, including a medical and family history and physical examination.[45] Before starting pharmacotherapy for ADHD in youth or adults, the clinician should consider a baseline electrocardiogram (ECG) and consultation with a cardiologist if past medical history or family history suggests cardiovascular disease.[3,98,99]

Growth

The impact of ADHD medications on growth has been investigated extensively over the past 40 years as dose-dependent growth deficits of 1 to 1.4 cm/year have been observed with short-term stimulant treatment, mainly in the first 2 years. Weight deficits are more prominent with a mean 3 kg (6.6 lbs) weight decrease in the first year of treatment and 1.2 kg (2.6 lbs) weight decrease in the second year of treatment according to the MTA data.[102] Long-term studies on stimulants have reported divergent effects on growth, with many studies showing no clinically significant height deficits by adulthood. MTA study investigators assessed the largest cohort of children with ADHD ranging from 7-9 years old to 25 years old (*n*=515) and compared them to classmates without ADHD (*n*=258). These authors reported an overall adult height deficit of 4.7 cm among those consistently taking stimulant medication compared to those not taking a stimulant. Growth deficits were less when stimulants were taken inconsistently. Those taking stimulants consistently were 2.36 cm ± 1.13 cm shorter than those in the “inconsistent” group. Proposed mechanisms of stimulant effects on growth include alterations in growth hormone or growth factor, decreased thyroxine secretion, and suppression of appetite leading to reduced caloric intake.[45,102]

If symptoms can be managed with medication during weekends or summers, a medication-free trial may be considered every year.[45] Time off stimulant lessens stimulant growth suppressant effects, but evidence is lacking to firmly determine the impact of medication holidays on growth.[5,102] Consideration must be given to the risks of untreated ADHD symptoms on learning, socialization, and self-image while off stimulant therapy when determining the frequency and duration of the medication-free trial.[7,103] Medication dosage often varies from year to year, largely because of age-related pharmacokinetic changes. As a child develops, hepatic metabolism slows, and volume of distribution increases.[7]

Other

Cases of stimulant-induced peripheral vasculopathy, including Raynaud’s phenomenon, have been reported and are related to the peripheral release of catecholamines, resulting in vasoconstriction. Symptoms are typically intermittent and mild but can include digital ulceration and/or soft tissue breakdown. A retrospective, case–control study demonstrated that among children treated with stimulants, there was a significant association between the development of Raynaud’s phenomenon and past or current use of stimulants.[104] This risk is dose-dependent, with symptoms typically resolving after dose reduction or discontinuation of the medication.[92,105] Additionally, there is a case report of dose-dependent Raynaud’s phenomenon with atomoxetine use.[106] Close monitoring for digital changes is necessary during treatment with stimulants, α_2-adrenergic agonists, and atomoxetine/viloxazine. Rheumatology consultation may be required for some individuals.

Nonstimulants

Compared to the simulants, nonstimulant medications used for the treatment of ADHD are less effective alternatives than simulants in both children and adolescents. However, for most of these agents, the FDA has approved them both as monotherapy and as adjuncts to stimulants in children and adolescents for improving overall response and for managing behavioral symptoms and insomnia associated with ADHD. Some have also received FDA for the treatment of ADHD in adults. Potential advantages of non-simulants relative to stimulants include reduced potential for physical dependence or misuse, less potential for growth effects, and less sleep disturbance.[45] See Table 82-4 for dosing. Antipsychotic use is primarily for symptoms related to comorbid aggression, mood disorders, tics, or irritability associated with ASD and not for the core symptoms of ADHD.

TABLE 82-4

Dosing and Adverse Medication Reaction Monitoring of Nonstimulant Medications often used in ADHD

	Dosing Range and Titration Schedule	Adverse Reaction Monitoring
Serotonin norepinephrine reuptake inhibitors		
Atomoxetine (Strattera)	≤70 kg (154 lb): start at 0.3-0.5 mg/kg every AM or twice daily, maximum: 1.4 mg/kg/day; ≥70 kg (154 lb): start at 40 mg every AM or divided twice daily, maximum: 100 mg/day	Nausea, anorexia, ↑ blood pressure, ↑ pulse, insomnia, fatigue, sedation, severe liver injury (rare), suicidality
Viloxazine (Qelbree)	6-11 years: start at 100 mg/day. 12-17 years: start at 200 mg/day. Titrate in 100 mg increments/week, maximum: 400 mg/day	Nausea, vomiting, decreased appetite, sedation, insomnia, irritability, ↑ blood pressure, ↑ pulse, suicidality
Bupropion (Wellbutrin SR, XL)	50-300 mg/day; 3 mg/kg/day by end of week 1; can increase to 6 mg/kg/day or maximum of 300 mg/day as tolerated	Nausea, insomnia, rash, tics; dose-related risk of seizures
Antipsychotics (for comorbid aggression, mood disorders, tics, or irritability associated with ASD)		
Aripiprazole (Abilify)	2-5 mg daily; can titrate weekly as tolerated to response (usual range: 5-20 mg/day)	Nausea, restlessness, insomnia extrapyramidal symptoms, dizziness, sedation
Haloperidol[a] (Haldol)	0.5-1 mg twice daily; can titrate every 3-4 days as tolerated to response (usual range: 0.5-5 mg/day)	Extrapyramidal symptoms, dizziness, ↑ serum prolactin, sedation
Olanzapine[a] (Zyprexa)	2.5-5 mg every day; can titrate every 3-4 days as tolerated to response (usual range: 7.5-15 mg/day)	Sedation, severe weight gain, restlessness, extrapyramidal symptoms Diabetes, marked hyperlipidemia (never a first-line treatment)
Quetiapine[a] (Seroquel)	25-50 mg twice daily; can titrate every 3-4 days as tolerated to response (usual range: 200–600 mg/day)	Sedation, dizziness, weight gain, diabetes, hyperlipidemia
Risperidone[a] (Risperdal)	0.25-0.5 mg twice daily; can titrate every 3-4 days as tolerated to response (1-4 mg/day)	Extrapyramidal symptoms, dizziness, ↑ serum prolactin, decreased skeletal bone mass, hepatotoxicity, weight gain Diabetes, hyperlipidemia
Ziprasidone[a] (Geodon)	10-20 mg twice daily; can titrate every 3-4 days as tolerated to response (usual range: 40-160 mg/day)	Nausea, restlessness, insomnia extrapyramidal symptoms, sedation, QTc prolongation
Others		
Bupropion (Wellbutrin SR, XL)	50-300 mg/day; 3 mg/kg/day by end of week 1; can increase to 6 mg/kg/day or maximum of 300 mg/day as tolerated	Nausea, insomnia, rash, tics; dose-related risk of seizures
Alpha-2 adrenergic agonists		
Clonidine (Catapres) or	0.05 mg two or four times daily; can increase as tolerated to 0.1-0.4 mg/day. For	Sedation, dizziness, heart block (check ECG),

clonidine extended-release XR (Kapvay)	XR, give 0.1 mg at bedtime; may increase by 0.1 mg weekly; maximum: 0.4 mg/day given twice a day if dose >0.2 mg/day	constipation, headache, upper abdominal pain
Guanfacine (Tenex) or guanfacine extended-release XR (Intuniv)	0.5 once or twice daily; can increase as tolerated to 1-4 mg/day. Max: 4 mg/day in children/adolescents	Same as above with potentially lower risk of sedation. Effective dose higher in heavier children
	For XR, give 1 mg in the AM; titrate weekly to response; Max: 4 mg/day in children; 7 mg/day in adolescents	

[a] Short-term use (1-4 months) only for severe aggression associated with ADHD; may be longer if comorbidity such as bipolar disorder, Tourette disorder, or autism spectrum disorder.

ADHD, attention deficit/hyperactivity disorder; ASD, autism spectrum disorder; ECG, electrocardiogram; SR, sustained release; XL, extended length.

Data from References [42, 45, 97, 100, 105, and 107].

Atomoxetine

Atomoxetine is a selective norepinephrine reuptake inhibitor that should be taken in divided doses in the morning or late afternoon by children for improved tolerability.[108] Adults can take it once daily, usually in the morning.[108,112] Placebo-controlled, short-term trials (6-12 weeks) have shown that atomoxetine is effective in reducing ADHD symptoms in children, teens, and adults, and long-term studies show ongoing benefit and safety for children and adolescent responders out to 4 years.[96,97,109,112] A controlled trial comparing atomoxetine, OROS methylphenidate, and placebo over 6 weeks in 6- to 16-year-old patients showed that both medications were significantly better than placebo at improving ADHD symptoms, but OROS methylphenidate was superior to atomoxetine.[108,112] There was evidence for a preferential response to atomoxetine over stimulants in some individuals.[108]

Atomoxetine has a significantly slower onset of therapeutic effect than stimulants (2-4 weeks vs 1-2 hours with an effective stimulant dose), and full benefit may not be seen for 6 to 12 weeks.[108,109] The practice of combining atomoxetine with a stimulant in partially responsive patients is based on limited data from open trials and case series describing fewer late-day rebound effects and better sleep when atomoxetine is given in the evening; however, the adverse effects are additive.[108,109]

Possible adverse effects of atomoxetine and their management are similar to those of stimulants, including upset stomach and psychiatric and cardiac adverse effects (see Table 82-4 and "Psychiatric” and “Cardiac" sections). Although atomoxetine has less potential for growth suppression compared with stimulants, it has a greater risk of fatigue, sedation, and dizziness compared with stimulants or bupropion. Studies show that adults experience overall similar adverse effects as youth but they are less likely to report decreased appetite and are more likely to report urinary hesitation/retention and sexual adverse reactions (decreased libido and erectile disturbances) compared to youth.[109] Unlike stimulants, atomoxetine labeling includes a bolded warning of potential severe liver injury based on two cases (one adult, one child) of hepatic injury leading to transplant. A comprehensive safety review over 10 years described 133 cases of liver injury “possibly” related to atomoxetine, with liver functioning returning to normal after atomoxetine discontinuation. Although hepatotoxicity is considered rare, patients and families should be counseled to report signs of liver injury including dark urine, jaundice, or right upper quadrant pain.[96,109]

Viloxazine

Viloxazine is a selective norepinephrine reuptake inhibitor, FDA approved for patients 6 to 17 years with ADHD. Compared to atomoxetine, viloxazine is a less potent inhibitor of the norepinephrine transporter. In addition to norepinephrine reuptake inhibition, viloxazine increases 5-HT levels in the prefrontal cortex via modulation of serotonin receptors.[110] Viloxazine extended release capsules are administered once daily in the morning and can be opened and sprinkled onto applesauce.[100]

Improvement in ADHD symptoms was apparent at week 1 in clinical trials, suggesting a possible quicker onset of effect compared to atomoxetine.[111–113] Given viloxazine’s unique mechanism of action, there is interest in evaluating its role for comorbid depressive and anxiety symptoms.[110] Notably, viloxazine is a strong CYP1A2 inhibitor.[100]

The most common adverse effects associated with viloxazine include somnolence, decreased appetite, nausea/vomiting, insomnia, and irritability.[100] Changes in heart rate and blood pressure should be monitored after initiation and as the dose is titrated (see Table 80-4 and "Cardiac" section). Viloxazine, like atomoxetine, has a boxed warning for emergence of suicidal thoughts and behavior.[100]

α_2-Adrenergic Agonists

Guanfacine and clonidine are central α_2-adrenergic agonists, acting both presynaptically to inhibit norepinephrine release and postsynaptically to increase blood flow in the prefrontal cortex, which enhance working memory and executive functioning. Pharmacologically, both of these medications affect a multitude of neurotransmitter systems, including catecholamine, indolamine, and α_2-adrenergic receptors on parasympathetic neurons, opioids, imidazole, and amino acid systems.[78,97]

⑦ Guanfacine has a longer elimination half-life and duration of action (18 hours) compared with clonidine (12 hours), and its greater selectivity for the α_{2a}-adrenergic receptor, compared with clonidine, imparts less sedation and dizziness.[97] Clonidine and guanfacine are not as effective as stimulants for monotherapy treatment (effect size 0.22-0.58 vs 0.8-1.2 for stimulants).[97] In addition to being approved as monotherapy, extended-release clonidine and guanfacine are FDA approved as adjuncts to stimulants in children and adolescents. Therefore, both are prescribed frequently as adjuncts to reduce disruptive behavior, control aggression or improve sleep in youth.[5,97] Neither have been studied sufficiently for ADHD in adults.

Guanfacine XR can be given once daily during monotherapy while clonidine XR should be given twice daily for optimal symptom coverage. Both are considered acceptable second-line agents for children and adolescents unresponsive to or unable to tolerate stomach upset or insomnia with stimulant medications. Extended-release guanfacine and clonidine are more sedating than stimulants or atomoxetine; therefore, sleepiness during the school day requires careful monitoring.[97] Immediate-release α_2-adrenergic agonists are increasingly used to treat symptoms of ADHD in adolescents within the criminal legal system and adults due to no risk of physical dependence and potential benefits in controlling aggression and impulsivity, but this practice requires further study.[114]

The most common adverse medication reactions of clonidine and guanfacine are dose-dependent sedation, hypotension, and constipation.[4,5,97] The sedation seen with treatment usually subsides after 2 to 3 weeks of therapy.[97] Clinical trials show a mean decrease of 3 to 5 mm Hg in blood pressure with mean heart rate decrease of 3 to 5 beats/min. Both heart block and sudden death have been reported rarely with α_2-adrenergic agonists, and further analysis revealed that these events occurred in the context of polypharmacy and/or congenital heart malformation. Regardless, prescreening for existing cardiac problems and increased monitoring when combining medications is warranted.[45,97] Peripheral vasculopathies are well documented with α_2-adrenergic agonists, given their effects on peripheral catecholamine release; however, close monitoring and consideration of a rheumatology referral is warranted should these adverse events occur.[92,105]

Bupropion

Bupropion, a monocyclic antidepressant, is a weak dopamine and norepinephrine reuptake inhibitor with no significant direct effect on serotonin or MAO. Its active metabolites augment noradrenergic and dopaminergic function. While not FDA approved for the treatment of ADHD, investigations with bupropion in children and adolescents demonstrated efficacy greater than placebo in two controlled trials and efficacy comparable with methylphenidate in two separate controlled trials ($n = 18$ and $n = 44$).[114] Bupropion has been found beneficial for adolescents with depression and ADHD and causes less appetite suppression and weight loss compared with stimulants, but it has a greater risk of seizures.[114] An analysis of data evaluating bupropion for ADHD in adults show it is significantly more effective than placebo and modafinil but less effective than methylphenidate or amphetamine salts.[71]

Bupropion's adverse effects include nausea, which can resolve over time or with slower dosage titration, and rash, which can require discontinuation of therapy if severe (see Table 82-4). Due to an elevated risk of seizures, bupropion should not be used in patients with a seizure or eating disorder. Additionally, it can cause or exacerbate tics and should be dosed early in the day to minimize the risk of insomnia.[114]

Lithium and Valproate

Lithium or valproate can be used to control aggression and explosive behavior in patients with a co-diagnosis of ODD or CD, or those who are not responsive or are only partially responsive to treatment with a stimulant. Given the symptoms heterogeneity and overlap between some mental illnesses, some patients actually have childhood-onset bipolar disorder or combined ADHD–bipolar disorder.[77] Limited data show lithium is ineffective for ADHD alone but it is more likely effective when bipolar disorder coexists with ADHD.[77] Valproate is the most well-studied antiseizure medication (ASM) for aggression associated with ADHD. Dosing starts in low divided doses with titration over 1 to 2 weeks to therapeutic response.[115] See Chapter 75, "Epilepsy," for a more extensive discussion regarding adverse events for ASMs and Chapter 89, "Bipolar Disorder," for lithium.

Antipsychotics

First-generation antipsychotics such as chlorpromazine and haloperidol can improve symptoms of hyperactivity and impulsivity in children with ADHD, but their negative effects on learning, cognitive functioning, and the significant risk of extrapyramidal adverse reactions (eg, dystonia and tardive dyskinesia) limit their usefulness.[107]

Second-generation antipsychotics such as risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole have been used to control severe aggression in refractory cases of ADHD, particularly if CD or bipolar disorder coexists.[9,115] In general, the second-generation antipsychotics pose a lower risk of extrapyramidal adverse reactions compared with conventional agents, but they can cause metabolic adverse reactions such as hyperlipidemia, hyperglycemia, and weight gain in addition to hyperprolactinemia.[107] Ziprasidone has the lowest risk of metabolic adverse reactions among these second-generation antipsychotics. Risperidone is the most well studied for aggression associated with ADHD,[70] but because it has the most potent dopamine antagonism and poses the highest risk of hyperprolactinemia and associated early puberty, gynecomastia, galactorrhea, amenorrhea, and decreased bone density.[70,107,116] Aripiprazole is least likely to elevate prolactin due to its dopamine agonist effects.[107] See Chapter 87, "Schizophrenia," for a more thorough discussion regarding the antipsychotics and their adverse effects.

Comorbidity and Polytherapy in ADHD

(8) As previously stated, individuals with ADHD often present with comorbid conditions (Fig. 82-1), which may make polytherapy attractive or necessary. But this can complicate monitoring of therapy, because if multiple medications are started simultaneously, it is impossible to determine the impact of each medication. In general, the predominance and urgency of symptoms guide the medication selection process. For example, if a child presents as severely anxious or depressed with associated attentional problems, then an antidepressant should be initiated first with monitoring to determine if attentional symptoms improve.[4,76] When a child presents with severe ADHD and associated anxiety or depression, a stimulant should be initiated to treat the more severe ADHD. If ADHD symptoms improve significantly, but anxiety or depression persists, then an antidepressant can be added.[4,76] Studies show that stimulants do not routinely make anxiety disorders worse, but they might not improve symptoms either.[7,76]

Bipolar Disorder

(9) Childhood bipolar disorder may be difficult to distinguish from ADHD because inattention, hyperactivity, and impulsivity are common with both conditions. When ADHD is diagnosed in an individual with bipolar disorder, the mood must be stabilized first with lithium, an ASM, or an second generation antipsychotic before considering an ADHD-specific treatment.[77,115]

Autism Spectrum Disorders

Autism spectrum disorders are estimated to occur in 20% to 50% of youth with ADHD and 30% to 80% of youth with ASD exhibit symptoms of inattention.[117] Impairments can range from mild to severe with poor language development, poor social skills, sensory over-responsivity, emotional dysregulation, inattention, impulsivity, irritability, oppositional behavior, and aggression.[117] There are few studies to guide treatment of ADHD in individuals with ASD. A Cochrane review of four US randomized controlled trials involving 113 youth with ASD and ADHD treated with methylphenidate for 4 to 6 weeks demonstrated short-term benefit for hyperactivity and possibly inattention in children who could tolerate methylphenidate. Of note, youth who could not tolerate a test-dose were excluded, and there was no evidence that methylphenidate was helpful for social interaction or stereotypical behaviors.[118]

Available evidence shows that stimulants can be an effective treatment strategy in pediatric patients with ASD, but are less effective and less well-tolerated for managing ADHD in youth with more severe forms of ASD or with comorbid intellectual disability.[117–119] Atomoxetine was only slightly better than placebo in managing ADHD symptoms in children with ASD according to a 8-week controlled trial that included 97 children between the ages of 6 and 17 years.[72] Clonidine and guanfacine have small, uncontrolled studies only showing benefit in improving attention and decreasing aggressive/impulsive behavior in children with ASD.[117]

The AAP ASD guidelines recommend starting with a low-dose stimulant and monitoring carefully for worsening stereotypies, obsessional symptoms, sleep difficulties, poor appetite, depressive symptoms, social withdrawal, irritability, or the emergence of seizures.[119] If the stimulant is ineffective or poorly tolerated guidelines recommend atomoxetine, particularly if comorbid social anxiety, or an α_2-adrenergic agonist.[117]

Seizure Disorders

Patients with ADHD are two to three times more likely to experience seizures than age-matched peers, and ADHD is the most common comorbidity in youth with epilepsy.[120] While some reviews have demonstrated seizure aggravation and EEG changes related to stimulant treatment, most studies show methylphenidate is safe and effective for managing ADHD in youth with epilepsy.[120–122] A retrospective review of 18,000 Medicaid-enrolled youth with epilepsy and ADHD treated with a stimulant did not demonstrate an increased risk for seizure-related hospitalizations among current or former stimulant users.[123] Given the risk for stimulants to lower the seizure threshold, all individuals should be stabilized and seizure-free on an ASM prior to initiation of the stimulant.[76,123,124] Notably, valproate use may worsen attentional issues in children with ADHD. Additionally, antiseizure medication polytherapy may be associated with an increase in behavioral problems, although this may be attributed to more severe underlying neurologic symptoms.[120] If new or worsening seizures are suspected, discontinuation of the stimulant should be considered and cautiously reintroduced once stabilized.[60] The impact of atomoxetine, viloxazine, clonidine, and guanfacine on seizure frequency requires further study.[120,124] Bupropion use is contraindicated in patients with a seizure disorder.

Substance Use Disorders

The prevalence of SUD in adults with ADHD is estimated nine times higher than in those without ADHD.[125] Genetics, age (14- to 25-year-olds), psychosocial factors, and comorbidities all influence one's risk for SUDs,[46,126] with ADHD itself being a known risk factor for the development of an SUD. Among individuals with ADHD, persistent symptoms, a diagnosis later in adolescence or adulthood, and co-occurring diagnoses of ODD/CD are known predictors of developing an SUD.[127] A large Danish population-based cohort study (*N*=13,116) investigated risk factors for SUD development among individuals with ADHD. Results indicated that age greater than or equal to 13 years at first ADHD diagnosis (OR=3.28) and comorbid ODD/CD (OR 2.87) were most strongly associated with SUD development. Male sex and parental factors (eg, SUD, psychiatric condition, low paternal income and education) were also identified risk factors.[127]

A review of 27 longitudinal studies that followed children with and without ADHD into adolescence or adulthood found that compared with control subjects without ADHD, children with ADHD were (1) nearly three times more likely to report nicotine use in adolescence/adulthood, (2) almost two times more likely to meet diagnostic criteria for alcohol use disorder, (3) approximately 1.5 times more likely to meet criteria for cannabis use disorder, (4) twice as likely to develop cocaine use disorder, and (5) more than 2.5 times more likely to develop an SUD overall.[10,126] Observational follow-up of the MTA has provided additional information regarding long-term substance use in children with ADHD. As reported on the Substance Use Questionnaire (SUQ), youth with ADHD compared to their peers were more likely to use cannabis weekly (32.8% vs 21.3%) and cigarettes daily (35.9% vs 17.5%) as adults. Additionally, early substance use, specifically the use of alcohol, cigarettes, and cannabis, was more common in the ADHD group compared to peers.[10] This highlights the need for early substance use screening in adolescence, particularly among those with ADHD.[10]

⑩ Caregivers frequently express concern that treating their child with a stimulant, particularly early treatment, may increase the risk of substance use. Follow-up studies show that stimulant therapy for ADHD neither increases nor decreases the risk of subsequent SUDs.[10,46] There is evidence that individuals initiating treatment early (before age 8) are less likely to use substances than those who have delayed onset of treatment. Behavioral therapy may also confer some protection against substance use and issues with the criminal legal system.[10,46,126] Atomoxetine, an α_2-adrenergic agonist, or bupropion is preferred the agent for individuals with ADHD and active SUDs.

Furthermore, other comorbid conditions including depression, anxiety, low self-esteem, CD, ODD, and antisocial personality disorder all increase the risk for developing an SUD in an individual with ADHD.[10,126,127] These comorbidities also increase the risk for issues with the criminal legal system that can prevent treatment and lead to ongoing SUDs. As youth with ADHD transition to adolescence, parents and clinicians should pay attention to whether the teen could be at risk for an SUD or misuse of their prescribed medications.[126,128,129]

Several studies have evaluated protective factors against substance use and issues with the criminal legal system for youth both with and without ADHD. These studies found that a quality parent–youth relationship, involving good communication, regular time together, consistent rules, and sharing of information (eg, how the child or adolescent spends free time and who their friends are) can be effective in deterring alcohol and substance use in youth with or without ADHD.[46,126] Youth support groups at high schools, such as the Gay/Straight Alliance (GSA), are credited with assisting schools with achieving lower rates of substance use and the misuse of the prescribed ADHD medications compared with schools without GSAs.[128]

Eating Disorders

All patients with ADHD should be screened for eating disorders given inattention and impulsivity associated with ADHD increase the risk of aberrant eating behavior and obesity. Inattentive symptoms can lead to mindless eating when not hungry, or impulsive, out of control eating aimed at emotional regulation.[130,131] A meta-analysis of 728,136 participants, 48,161 with ADHD (46,115 children; 2046 adults), and 679,975 comparison subjects (616,228 children; 63,747 adults) showed that the pooled prevalence of obesity was increased by about 70% in adults with ADHD and 40% in children with ADHD. A genetic association has been found with non-restricting eating disorders such as bulimia nervosa and binge eating disorder, particularly in females.[132] Lisdexamfetamine is an FDA-approved effective treatment for both ADHD and binge eating disorder in adults.[133,134]

Oppositional Defiant and Conduct Disorders

Oppositional defiant disorder and CD occur in 30% to 60% of youth diagnosed with ADHD and are commonly associated with severe aggression and functional impairment.[135] Causes of ODD, CD, and associated severe aggression in youth with ADHD are multifactorial and include psychosocial adversity factors (eg, maternal mental disorder, paternal criminality, violence in the home), learning disability, disruptive mood dysregulation disorder (DMDD), or bipolar disorder.[135–137] Experts consider psychosocial interventions that include parent training and support for the child's family an essential part of the treatment plan for youth with ADHD, co-occurring with ODD or CD.5[42,60,137–141]

Effective treatment of ADHD and CD/ODD is critical in the reduction of a wide range of psychosocial consequences (eg, substance use, violence, unemployment). Evidence-based guidelines recommend stimulants as first-line treatment for oppositional behavior, conduct problems, and aggression in youth with ADHD and comorbid CD/ODD.[138–140] Optimization of stimulant monotherapy (particularly methylphenidates) has demonstrated rapid, long-lasting improvements in emotion dysregulation, aggression, and ADHD symptoms.[142–144] A 2-year follow-up study of youth ($n = 33,835$) with ADHD found that patients with higher rates of adherence to stimulants or atomoxetine were less likely to eventually develop CD/ODD compared to those with poorer adherence, suggesting a possible protective effect of medication treatment.[145]

Studies in adolescents and adults with ADHD show that doses of stimulant above the recommended daily maximum are frequently needed for optimal symptom control prompting the American Academy of Child and Adolescent Psychiatry to publish an "off-label maximum dosage of 100 mg/day for methylphenidate and 60 mg/day for dextroamphetamine and mixed amphetamine salts." These dosage ranges appear in the academy's practice parameter on the treatment of ADHD.[42]

A head-to-head, randomized, 24-week open-label trial among youth treated with atomoxetine ($n = 80$) or OROS-methylphenidate ($n = 80$) demonstrated improvement in emotional/behavioral/externalizing problems in youth, with greater improvement in aggressive behavior and conduct problems in the OROS-methylphenidate group.[146] Treatment guidelines recommend that atomoxetine be considered in individuals who do not respond to or poorly tolerate stimulants.[138–140] Clonidine and guanfacine can be considered as monotherapy or add-on to stimulant treatment, but evidence to support their use is much lower quality.[138,139]

Unfortunately, optimizing ADHD-specific medications such as stimulant or atomoxetine is not universally effective for aggression and over half of youth with ADHD and ODD/CD need more than one medication for optimal symptom control.[70] The treatment of severe childhood aggression (TOSCA) study included 168 youth with ADHD and either ODD or CD (mean age of 9 years) and showed that adding risperidone 1 to 3 mg daily to parent training, behavioral therapy, and optimized stimulant resulted in moderate improvement in aggression. A 52-week follow-up of study participants demonstrated an overall benefit for youth who remained on medication, with the risperidone augmented-group demonstrating a small added benefit (improved CGI-S scores). This warrants close evaluation considering the long-term use of risperidone was associated with significant increased risk for weight gain and increased serum prolactin.[147] Overall, guidelines recommend that risperidone should be considered as a short-term treatment for severe aggression and/or explosive anger if not effectively managed by traditional ADHD medications.[138,139]

Aggression

Aggressive behavior is a common reason children present to higher levels of psychiatric care and is most prevalent in children with ADHD, often combined with ODD, CD, or DMDD.[148,149] Stimulants are typically considered first line for co-occurring aggression and ADHD, with some pediatric patients requiring adjunct pharmacologic treatment (eg, second generation antipsychotic, mood stabilizer).[149] A randomized, controlled trial including 6- to 12-year-olds (*N*=175) with ADHD, a disruptive disorder, significant aggression, and prior stimulant treatment demonstrated significant reduction in aggression (63% experienced remission) with rapid symptom-guided stimulant titration. This suggests that quick optimization of stimulant treatment and concurrent behavioral therapy may minimize the need for additional medications. For those who do not experience a significant reduction in aggression, adjunctive medications like risperidone and valproate may be helpful but are associated with risk (eg, weight gain).[149]

Tourette Disorder

ADHD occurs in 50% to 60% of youth with chronic tics or Tourette disorder, and 20% of children with ADHD go on to develop chronic tics or Tourette disorder.[72,73,91] Experts cautioned that stimulants should not be first-line treatments for ADHD in youth with tic disorders due to the stimulant's ability to increase central dopaminergic and noradrenergic activity, potentially exacerbating tics. However, a meta-analysis of 22 placebo-controlled trials involving 2,385 children with ADHD and Tourette disorder showed that stimulants were not more likely to worsen tics than placebo, and the association between stimulants and new-onset tics was more coincidental than a cause-and-effect relationship.[91] Additionally the timing of tic development in the context of ADHD may have led clinicians to inappropriately attribute new onset tics to stimulant treatment, as epidemiologic studies show that when ADHD and Tourette co-occur, symptoms of ADHD are present 2 to 3 years before tics emerge. Tourette disorder is known for fluctuating symptom severity with tics worsening and remitting in an unpredictable pattern, further diminishing the ability to accurately attribute tic causality.[75,91] When a stimulant trial is necessary to manage functionally impairing ADHD in a person with Tourette disorder, methylphenidate is recommended due to better evidence for effectiveness and tolerability in this population.[150]

A double-blind, placebo-controlled trial compared methylphenidate or clonidine monotherapy with the combination of methylphenidate and clonidine in patients with ADHD and Tourette disorder. Combination therapy demonstrated the greatest benefit in reducing symptoms of ADHD and tics, and clonidine appeared most helpful for impulsivity and hyperactivity, whereas methylphenidate was most helpful for inattention.[75,91] All treatments were well tolerated, but sedation was common (28%) in those receiving clonidine.[75]

Furthermore, guanfacine was administered to 34 children (mean age 10.4 years), with ADHD and tic disorder during an 8-week, placebo-controlled trial at a dose of 1.5 to 3 mg/day. Tic severity decreased by 31% in the guanfacine group compared with 0% in the placebo group.[75] There was a mean improvement of 37% on the teacher-rated ADHD scale compared with 8% improvement with placebo. Therefore, as previously stated, clonidine or guanfacine alone is a less effective alternative to stimulants in the treatment of children with ADHD and this holds true for those with comorbid Tourette disorder.

Atomoxetine appears to be an effective treatment for ADHD and tics in pediatric patients with comorbid Tourette syndrome or chronic motor tic disorder. For this study, 148 children and adolescents were randomized to atomoxetine (0.5-1.5 mg/kg/day) or placebo for up to 18 weeks of treatment. Overall, atomoxetine resulted in improvements in the severity of ADHD (effect size = 0.6) and tics (effect size = 0.3).[109]

Individuals with Tourette disorder and ADHD are more prone to disruptive behaviors including poor frustration tolerance, aggression, and impulsivity, often requiring behavioral interventions and medications that may include second-generation antipsychotics.[75] Second-generation antipsychotics such as risperidone, aripiprazole, and ziprasidone have evidence from controlled trials to support their use in managing motor and vocal tics associated with Tourette disorder; however, aripiprazole is the only agent FDA approved for managing Tourette disorder.[75] See Chapter 87 for more information about antipsychotics.

Personalized Pharmacotherapy

There are many things to consider when making therapeutic decisions in patients with ADHD such as age, comorbidities, tolerability, potential for medication interactions, and patient preference. In addition, there may be pharmacokinetic and pharmacogenomic factors to consider when personalizing pharmacotherapy. In looking specifically at pharmacogenomics, the functional activity of cytochrome P450 (CYP) 2D6, norepinephrine and dopamine transporters (SLC6A2, SLC6A3), catechol-*o*-methyltransferase (COMT), dopamine receptor (DRD4), carboxylesterases (CES1), and α_2-adrenergic receptor (ADRA2A) has been evaluated as a predictive tool for ADHD medication response and tolerability.[151–155] As the pharmacogenomics of ADHD treatments is a rapidly evolving field, an evidence-based resource available to decipher this work is provided by the Clinical Pharmacogenomics Implementation Consortium (CPIC, www.cpicpgx.org) or the Pharmacogenomics Research Network (PGRN, www.pharmgkb.org).[156] Specifically, the CPIC website contains evidence-based expert guidelines for interpretation of specific gene drug pairs, which may be used when testing is completed. It is important to note that CPIC does not recommend testing, but rather aims to serve as a reference for when testing results are available.

A CPIC guideline is available to guide dosing of atomoxetine based on CYP2D6 genotype in pediatric patients.[157] Exposure to atomoxetine increases 10-fold among CYP2D6 poor metabolizers and has a longer half-life, 20 hours compared to 5 hours, resulting in increased total plasma exposure compared to normal metabolizers.[157] Some studies have shown that CYP2D6 poor metabolizers may experience more insomnia, weight loss, increased heart rate and blood pressure, constipation, and depression associated with atomoxetine treatment compared to extensive metabolizers.[158–160] Additionally, poor metabolizers may demonstrate greater therapeutic benefit due to increased exposure to the medication.[155,158] The CPIC guideline provides specific recommendations for starting doses based on CYP2D6 genotype and atomoxetine peak plasma concentrations and the manufacturer recommends dose adjustments based on genotype and concomitant treatment with potent CYP2D6 inhibitors.[157,160,161]

As methylphenidate is de-esterified by CES1 prior to elimination, it is less likely to have metabolic drug interactions compared with mixed amphetamine salts.[162] Sex influences the absorption of methylphenidate, with males having increased bioavailability compared with females.[7] Variability in dosage requirements for amphetamine salts, atomoxetine, and bupropion can be due to inter-individual variability in plasma concentration achieved at a given dose. As all are metabolized via CYP2D6, the bioavailability and half-life of CYP2D6 substrates can be four to eight times greater in those taking a CYP2D6 inhibitor (eg, bupropion, fluoxetine, or paroxetine).[158–160]

While the routine use of pharmacogenomic testing is not recommended prior to initiation of ADHD medication, consideration should be made in particular clinical scenarios: (a) prior to the initiation of atomoxetine in pediatric patients with previous poor response/tolerability to other substrates of CYP2D6 and/or who are particularly sensitive to changes in HR/BP; (b) poor tolerability to atomoxetine/stimulants at starting doses; (c) individuals presenting with several psychiatric comorbidities and a history of psychotropic medication poor response/tolerability; and (d) family history of poor medication tolerability.

EVALUATION OF THERAPEUTIC OUTCOMES

Careful documentation of baseline symptoms and complaints over a 1-month pre-medication period is essential to the evaluation of therapeutic and adverse outcomes. Investigation regarding family history of psychiatric disorders and cardiac disease is essential to determine risk for related adverse medication reactions and to implement appropriate monitoring.[45,60] Baseline symptoms can be measured using videotapes, clinician rating scales (eg, ADHD Rating Scale IV, Vanderbilt ADHD Diagnostic Scale), or both. In addition, height, weight, and eating and sleeping patterns should be recorded at baseline and every 3 months.[5,42,45,60]

After the initiation and titration of any medication treatment, it is necessary that caregivers, teachers, and clinicians assess the overall functioning of the child or adult using standardized rating scales to determine if significant therapeutic benefit justifies continuing medication.[4,42] Therapeutic effects of the stimulants include decreased motor activity and impulsivity and increased attention span.[4,7,42] This suggests that stimulants are indicated for ADHD symptoms and not for primary learning disorders. The benefits of medication therapy must outweigh the potential for adverse effects to justify continued treatment.[4,42]

There is a lack of standardized assessment tools for adults; however, the adult ADHD screening tool can be useful.[49] Short-term studies (1 year or less) in adults with ADHD show that treatment with stimulants improves subjective quality of life. Long-term studies are needed to better assess the risk versus benefit of stimulant therapy on psychosocial and health outcomes.[163]

Atomoxetine, α_2-adrenergic agonists, and bupropion also require monitoring to detect changes in appetite, weight, and sleep patterns, as well as pulse and blood pressure. A therapeutic trial of atomoxetine or bupropion consists of 6 weeks at maximum tolerated doses unless response occurs at a lower dose.[4,42] Atomoxetine's full therapeutic benefit may continue to build over weeks to months, but if there is no significant benefit in the initial 6 weeks, it is unlikely that atomoxetine will be effective; therefore, it can be tapered off.[109]

When guanfacine or clonidine is given, careful clinical monitoring for fatigue, dizziness, and autonomic changes (eg, blood pressure and pulse) is recommended.[45,97] The American Heart Association has stated that ECG monitoring is not required for α_2-adrenergic agonists treatment in children, although many clinicians continue to assess for ECG changes, particularly if there is a family history of cardiac disease, if the patient is taking other agents that impact cardiac function, or if clinical symptoms warrant.[45] When discontinuing treatment, clonidine and guanfacine should be withdrawn slowly (0.05 mg clonidine/0.5 mg guanfacine reductions every 3-7 days) to prevent rebound hypertension or behavioral dyscontrol.[97,164] A therapeutic trial requires 1 to 2 months to assess therapeutic response, although increased sleep usually occurs immediately.[97,164]

Evaluation of therapeutic outcomes is particularly important when antipsychotics are used in youth as the US Office of Inspector general's peer review of psychiatrists found quality of care concerns in 67% of 475 medical records of youth receiving antipsychotics through Medicaid.[165] Among the biggest problems were lack of appropriate indications and lack of appropriate monitoring to ensure safety. Baseline weight, lipids, and fasting glucose should be monitored every 6 months in addition to the need to monitor for extrapyramidal symptoms and hyperprolactinemia.[9,107,165]

CONCLUSION

ADHD is a heritable, well-studied brain disorder that can present at any age, with or without co-occurring conditions. It is best treated with a combination of psychosocial, educational, cognitive-behavioral, and pharmacologic interventions. Treatments should be selected based on age, co-occurring conditions, and patient/family preference.

SELF-ASSESSMENT QUESTIONS

1. A 4-year-old child exhibits severe hyperactivity at preschool and is asked to leave preschool due to aggression, impulsivity, and not following directions. Which of the following statements describes an additional diagnostic criterion needed for a diagnosis of ADHD?
    A. The symptom duration would need to be 6 weeks.
    B. These impairing symptoms are also present at home.
    C. The patient must be at least 6 years old.
    D. Learning disability needs to be ruled out.
2. A teacher's aide asks about the most likely cause of new onset tics (throat clearing) in a 9-year-old with ADHD and Tourette disorder treated with Quillivant 20 mg daily and clonidine 0.1 mg at bedtime (same doses for 3 months)? The best answer is:
    A. Too much sugar in the diet.
    B. Quillivant dose is too high.
    C. Clonidine dose is too low.
    D. Natural course of tic disorder.
3. A deficiency in this substance contribute to ADHD symptoms:
    A. Ferritin
    B. Cyanocobalamin
    C. Folate
    D. Ascorbic acid
4. Which statement should be included when counseling a family on the risks of stimulant therapy for ADHD?
    A. The risk of an adverse cardiac event is two times greater in a child taking stimulant compared to an untreated child.
    B. Stimulant therapy for ADHD increases the risk of accidental injury, including the risk of severe brain injury.
    C. The risk of decreased growth and insomnia is greater with immediate-release stimulants.
    D. Stimulants are more likely to be associated with severe liver injury compared to atomoxetine.
5. Which of the following statements most accurately describes the clinical presentation of adult ADHD?
    A. Hyperactivity and impulsivity are the most prominent symptoms.
    B. Adults frequently report racing thoughts, mood swings, and insomnia.
    C. Disorganization increases in frequency and severity over the adult life span.
    D. Distractibility and difficulty with sustained mental effort are most common.
6. What structural brain change is the most well-established marker for ADHD?
    A. Enlarged ventricles and diminished basal ganglia

B. Underdevelopment of the locus coeruleus

C. Overgrown lateral lobe of the amygdala

D. Cortical thinning and delay in cortical thickness

7. Which of the following is an appropriate starting dose of atomoxetine for a 10-year-old (100 lb [45 kg]) child with ADHD?

A. 20 mg twice daily

B. 25 mg in the morning

C. 10 mg twice daily

D. 30 mg at bedtime

8. A 12-year-old female diagnosed with ADHD and conduct disorder is suspended from school for cannibis use. The patient was started on lisdexamfetamine 6 weeks ago, but prescription records show only a 30-day supply was dispensed. Which factor is most likely to have contributed to an increased risk of substance use in this patient?

A. Comorbid conduct disorder

B. Diagnosis of ADHD

C. Female gender

D. Taking lisdexamfetamine

9. Which ADHD medication is most likely associated with excessive daytime sedation requiring counseling regarding possible sleepiness during the school day?

A. Lisdexamfetamine

B. Bupropion

C. Atomoxetine

D. Clonidine

10. Which of the following statements is accurate regarding the treatment of ADHD in a patient with autism spectrum disorder (ASD)?

A. Methylphenidate has the best chance for efficacy in less severe ASD

B. Risperidone is preferred as it can improve irritability and symptoms of ADHD

C. α_2-Adrenegic agonists may improve both ADHD symptoms and irritability

D. Atomoxetine is first-line treatment due to its ability to lessen anxiety over tics

11. A 23-year-old graduate student asks about the most potentially effective treatment for ADHD. The patient took some medication as a child but can't remember the name. Which treatment has the most chance for therapeutic benefit and ease of administration for this patient based on efficacy studies?

A. Mydayis ER

B. Aptensio XR

C. Metadate ER

D. Dyanavel XR

12. In a patient with bipolar disorder and severe inattention and hyperactivity, the following treatment plan is most appropriate:

A. Stabilize mood first with lithium or other mood stabilizer, and then consider whether low-dose stimulant is needed for inattention and hyperactivity.

B. Manage ADHD with bupropion, and then consider adding a mood stabilizer or second generation antipsychotic once ADHD symptoms are controlled.

C. Avoid stimulants as they will worsen mania; give atomoxetine to manage both ADHD and bipolar disorder.

D. Start extended-release guanfacine to manage ADHD and then consider adjunctive lithium or second generation antipsychotic.

13. Potential advantages of α_2-adrenergic agonists over stimulants for ADHD include:

A. More rapid onset of therapeutic effect

B. Less insomnia, anorexia, and growth effects

C. Greater efficacy for inattentive symptoms

D. Effective for children, teens, and adults

14. A 10-year-old with ADHD and conduct disorder with severe aggression is taking 54 mg of osmotically released oral delivery system (OROS) methylphenidate. BP is 116/68, pulse 60, weight is 50 kg (110 lb). What intervention has the most evidence for efficacy in managing aggression in this patient?

A. Increase dose of OROS methylphenidate to 72 mg

B. Add guanfacine 1 mg twice daily

C. Change from OROS methylphenidate to atomoxetine

D. Add risperidone 0.5 mg twice daily

15. Studies have shown that adjunctive behavioral interventions administered to youth with ADHD:

A. Are more effective than stimulant medications.

B. Are not likely to be administered in the classroom.

C. May allow for lower effective doses of stimulant.

D. Are more effective for inattention than hyperactivity.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** The *DSM-5* diagnostic criteria for ADHD states symptoms must be present for 6 months in two different settings such as home or school. A learning disability is a common comorbidity with ADHD but is not required for a diagnosis of ADHD. (See "Clinical Presentation" section.)

2. **D.** At least 50% of Tourette disorder patients have ADHD symptoms. Research investigating causes of tics has shown methylphenidate to be an unlikely cause, with most cases of symptom worsening due to the natural course of Tourette disorder.

3. **A.** Several studies have documented iron deficiency in children with ADHD. Iron supplementation has been associated with improvement in ADHD

symptoms.

4. **A.** Although rare, the risk of an adverse cardiac event is two times greater in those taking stimulant medication compared to untreated individuals. This makes sense based on the mechanism of action of stimulants, increasing sympathetic nervous system tone which can increase heart rate and blood pressure.

5. **D.** This is the correct answer because hyperactivity is a prominent symptom during childhood, not adulthood; disorganization is a symptom common in all ages. Mood swings and racing thoughts are not part of the ADHD diagnosis.

6. **D.** Functional and structural brain imaging studies show cortical thinning and a delay in attaining cortical thickness in the brains of persons with ADHD. Cortical thinning is evidence for lack of brain maturation. Lack of brain maturation is associated with the lack of ability to think before acting or poor impulse control.

7. **C.** Atomoxetine dosing recommendations call for a starting dose of 0.5 mg/kg/day, and studies show youth tolerate atomoxetine better when given in divided doses compared to once daily (see Table 82-2).

8. **A.** Conduct disorder is a well-established risk factor for developing a substance use disorder. Having a diagnosis of ADHD is a risk for developing a substance use disorder but the presence of conduct disorder poses a greater risk according to longitudinal studies such as the MTA study.

9. **D.** Lisdexamfetamine and bupropion may both be associated with insomnia. Atomoxetine can cause sleepiness in some individuals but clonidine is much more likely associated with sedation (see Tables 80-3 and 80-4).

10. **A.** Methylphenidate is the treatment with the most evidence for therapeutic benefit in improving ADHD symptoms in individuals with ASD.

11. **A.** Amphetamine-based products are the most effective agents for adults with ADHD according to the available literature. Mydayis and Dyanavel XR are amphetamine products. Aptensio XR and Metadate ER are methylphenidate-based products (see Table 82-2).

12. **A.** A mood stabilizer is first-line in patients with bipolar disorder even if they have comorbid ADHD. If a stimulant or atomoxetine are given without a mood stabilizer, manic and/or psychotic symptoms may be induced. Extended-release guanfacine has not been studied for bipolar disorder co-occurring with ADHD (see Fig. 82-1).

13. **B.** Clonidine and guanfacine are less effective alternatives to stimulants in children and adolescents. The onset of therapeutic effect is 2 to 4 weeks, and they have not been sufficiently studied to recommend for adults with ADHD.

14. **D.** Risperidone is the most well-studied and effective agent for managing aggression in patients with ADHD and conduct disorder. Increasing the OROS methylphenidate dose to 72 mg daily would be exceeding the maximum recommended dose in children below 12 years of age. Guanfacine is less likely to be effective compared to risperidone.

15. **C.** Several studies in school age youth and adolescents with ADHD show medications are generally more effective than behavioral interventions but behavioral interventions can allow for symptom improvement at lower doses.

Chapter 85: Substance Use Disorders I: Opioids, Cannabis, and Stimulants

Patrick Leffers; Brittany Johnson; Patrick Aaronson

KEY CONCEPTS

KEY CONCEPTS

① The financial impact of the opioid crises is estimated to have totaled $504 billion in 2015, which accounted for approximately 2.8% of the gross domestic product (GDP).

② Opioids accounted for over 70% of all overdose deaths in 2019. The Centers for Disease Control and Prevention (CDC) estimates each day at least 136 people in the United States die from an opioid overdose.

③ Between 2006 and 2012, opioid prescribing in the United States steadily increased with a peak annual opioid prescription count of 255 million prescriptions.

④ Opioid overdoses involving prescription opioids, synthetic opioids, and heroin have continued to increase while healthcare professionals, legislators, and the community have worked together to reverse this trend, by focusing on prevention, treatment, recovery, and enforcement.

⑤ The pathophysiology of opioid use disorder, as with other substance use disorders (SUDs), centers around the reward centers and mechanisms in the brain.

⑥ Opioid use disorder (OUD) is a chronic often relapsing condition. Viewing OUD as a disorder and providing medications for the treatment of OUD, patient education, and support have been shown to decrease the risk of accidental overdose or full relapse into opioid use.

⑦ There are three Food and Drug Administration (FDA)–approved medications used in OUD: buprenorphine, methadone, and naltrexone. All three medications have demonstrated superiority for substance use disorder over no treatment. Pharmacotherapy in combination with psychosocial therapy has been found to be more effective than either treatment alone.

⑧ Patients who achieve clinical stability have longer acting options that may improve adherence and quality of life.

⑨ While not a treatment for OUD, naloxone is an integral treatment option that has been shown to save lives. Naloxone is a mu-opioid receptor antagonist that can be used in the reversal of an opioid overdose. It can be administered by multiple routes and is available without a prescription in many states. Healthcare providers play an important educational role on the importance of naloxone use in an opioid overdose situation.

⑩ Benzodiazepine prescribing has increased by over 65% from 1996 to 2013 and continues to climb. Overdose rates have increased over sevenfold from 2002 to 2019, the peak occurring in 2017.

⑪ Symptomatic and supportive care is the standard of care for benzodiazepine intoxication. Flumazenil is an antagonizing antidote that can be considered in select overdose situations. Treatment of benzodiazepine withdrawal is similar to treatment of alcohol withdrawal.

⑫ Stimulants including cocaine, methamphetamines, and newer derivatives continue to pose a significant issue to the population. Treatment of acute intoxication from these agents centers on supporting vital functions, while treatment for chronic use is less well described for such stimulants.

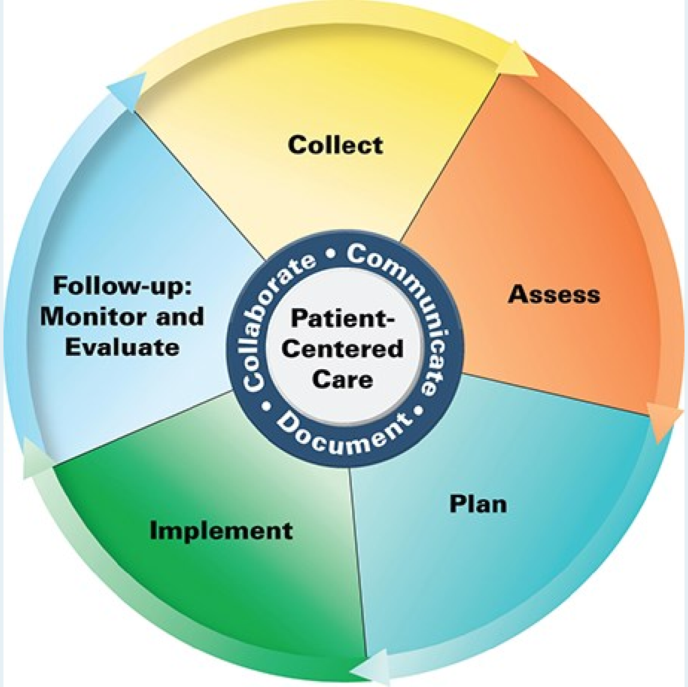
⑬ Expanded legalization of cannabis by individual states has brought an increase in chronic use. Emerging evidence supports the occurrence of an associated syndrome of effects known as cannabinoid use disorder (CUD). Treatment of CUD is in its infancy.

⑭ Cannabinoid hyperemesis syndrome (CHS) is a syndrome of cyclical vomiting in individuals with habitual use of cannabis that abates after discontinuation of use. The pathophysiology underlying CHS is not completely elucidated.

⑮ Many individuals who experience CHS report that hot showers improve symptoms, but that the benefit is short-lived. If intravenous fluids and traditional antiemetics are unsuccessful, other treatment options that are less established have been reported. Dopamine antagonists like haloperidol have been used successfully as well as topical capsaicin products.

PATIENT CARE PROCESS

Patient Care Process for Opioid Use Disorder (OUD)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

Objective Data

- Patient characteristics (eg, age, sex, pregnancy status)
- Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight
- Prescription drug monitoring program (PDMP) data
- Practitioner observed pill counts
- Labs including urine or oral fluid drug testing, pregnancy test, liver function tests (LFTs), Hepatitis B and C serology, Human Immunodeficiency Virus (HIV) serology

Medication history

- Current medications including herbal products, dietary supplements, over-the-counter (OTC) medications, nonprescribed medications, prescription medications, illicit substances
- Known medication allergies or intolerances

Past medical history

- Past or current co-occurring illnesses (physical and mental), injuries, surgeries, and hospitalizations
- General state of current physical and mental health (eg, good, fair, poor, concern for suicidal ideation)

Social and environmental history

- Substance use (eg, tobacco/ethanol use, substance use, prescribed and/or non-prescribed medication use)
- Opioid use history (eg, age of first use, frequency and recentness of use, routes of use, overdose history, medication and drug mixing, withdrawal, tolerance, history of treatment for substance use disorder [SUD])
- Problems resulting from substance use
- Participation in high-risk activities for contracting sexually transmitted infections (STIs)
- Living environment and transportation resources
- Education level completed and current employment status
- Current support systems (eg, family, friends, group therapy)
- Family history of SUD (eg, parents, siblings, partners)
- Childhood or adolescent abuse (eg, emotional, sexual, physical, verbal)

Assess

Signs of opioid intoxication or withdrawal

- Physical
  - Dental caries, perforated septum, skin abscesses, needle track marks, swollen extremities, withdrawal (eg, goose bumps, nausea, abdominal cramps, tearing, yawning, runny nose, yawning) or intoxication (eg, drooping eyelids, constricted pupils, reduced respirations, itching, head nodding)
- Neurological
  - Dilated or constricted pupils, slurred or rapid speech, agitation, insomnia, falling asleep at inappropriate times, unstable gait
- Psychiatric and Behavioral
  - Depression, anxiety, low self-worth, mental health disorders, feelings of hopelessness or loss of control, resentment
  - Use of other substances, conduct disorders, impulsivity, alienation from others, involvement with the criminal justice system
- Risk stratification
  - Assess patients for alcohol, tobacco, substance use, and substance use disorders

  - Screening tools and symptom surveys may aid in determining opioid risk (eg, Pain Medication Questionnaire, Opioid Risk Tool, Current Opioid Misuse Measure), opioid withdrawal (eg, Clinical Opioid Withdrawal Scale, Objective Opioid Withdrawal Scale), alcohol use disorder (alcohol use disorder identification test), and respiratory depression (Risk Index for Overdose or Serious Opioid-Induced Respiratory Depression).
  - The *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition* (*DSM-5*) criteria for diagnosis of SUD should be established by a provider prior to proceeding forward with treatment.
- Evaluate patient readiness
  - Highlight consequences that may motivate positive change
  - Identify patients' reasons to start treatment (eg, people, quality of life, self)
  - Determine the patients' preferred treatment setting (eg, opioid treatment programs, outpatient office visits with a prescriber)
  - Discuss potential barriers for patient access to treatment for OUD, mental health support, and laboratory tests for monitoring

Plan*

- Engage the patient in shared decision making regarding the risks and benefits of using medications to treatment of OUD, including alternative treatments
- Review medication options for the treatment of OUD (Tables 85-1, 85-2, and 85-3)
- Design a medication therapy regimen (eg, specific medication(s), dose, route, frequency, and anticipated duration of therapy (Tables 85-1–85-3, and 85-5)
- Communicate monitoring parameters including efficacy (eg, cravings, relapse, and withdrawal symptoms) and safety (eg, medication interactions, adverse medication effects); frequency and timing of follow-up
- Educate patients about their diagnosis, medication, and expectations (eg, purpose of treatment, possible adverse medication effects, importance of proper storage of medication, naloxone education, risk of overdose with discontinuation of treatment and return to substance use, notify other providers they are on this medication) (Table 85-4)
- Refer patient to other providers when appropriate (eg, behavioral health specialist, social worker)

Implement*

- Review all elements of treatment plan with the patient and their support system (eg, friends, family, significant others)
- Continue to engage the patient with motivational interviewing, establish patient centered goals and identify healthy coping strategies
- Provide a home naloxone device and complete proper education with the patient and their support system
- Schedule patient follow-up visit

Follow-up: Monitor and Evaluate

- Initiate individualized dosing focused on improving symptoms of withdrawal without over-sedation
- Titrate dosing over days to weeks to target cravings and blunt the euphoric responses from self-administered illicit opioids
- Assess patient for changes in health (eg, pregnancy, pulmonary disease, hepatitis) and medications, including those non-prescribed substances, prescribed medications, OTC, or herbals)
- Reevaluate medication therapy daily to weekly until stable

- Continue random drug testing, and monitoring for medication-related adverse medication effects

Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled "Opioid Overdose-Administration of Naloxone" by NIH Pain Consortium Centers of Excellence in Pain Education at Saint Louis University Edwardsville. This brief video provides an overview of the three FDA-approved naloxone delivery methods for the treatment of opioid overdose.

Determine if your state has approved use of cannabis for medical purposes and/or legalized recreational use. Determine if your state's governing board has issued a statement or policy about medical cannabis. Think about how your health system is affected by these state laws.

INTRODUCTION: OPIOIDS

In 1889, the Boston Medical and Surgical Journal published a piece by J.F. Adams, M.D., addressing the unique and indispensable place opium holds in the pharmacopeia. "While surpassing other remedies in its beneficent effects, it is alike remarkable in its power to harm. Hence, its medical use requires a degree of caution not less than that with which a surgeon handles a scalpel." Adams goes on to highlight his concerns with opioid use (eg, risk of overdose, significant side effect profile, and risk of dependence) advocating for judicious stewardship of these agents.[1] Negating Adams' previous concerns was a 1980 single paragraph letter to the Editor of the *New England Journal of Medicine* reporting the risk of physical dependence was rare in patients without a history.[2] A bibliometric analysis identified 600 citations of this letter occurring between 1981 and 2017. Interestingly, the majority of these citations occurred after the FDA approval of OxyContin© (extended-release oxycodone hydrochloride) in 1995.[3] OxyContin® promotion was done by targeting primary care providers claiming it was less addictive than traditional opioids. While this marketing sparked an exponential increase in prescribing, an intense morphine-like high could still be experienced when it was crushed and injected, snorted, or swallowed. This promotion of opioid prescribing and availability was further perpetuated in late 1990s by professional organizations (eg, American Pain Society, American Academy of Pain Medicine, and the American Geriatrics Society) who endorsed the use of opioids in chronic non-malignant pain.[4] In the early 2000s, the Joint Commission linked healthcare quality and patient satisfaction with pain control which prompted providers to take action in addressing patient reported pain scores. The overall result from this series of overlapping events was increased opioid prescribing, increased non-medical use of prescription opioids, and an increase in opioid-related deaths.

In an attempt to regain equilibrium, national and global health organizations allocated efforts and resources to addressing what was now a public health issue. Clinical guidelines and safety measures regarding controlled substance prescribing, prescription drug monitoring programs, education on proper storage and disposal of opioids, and take-home naloxone were expanded.[5] While these actions resulted in decreased opioid prescribing beginning in 2006, opioid-related overdose deaths continued to increase. An epidemic once fueled by the use of pharmaceutical opioids is now overshadowed by illicit manufactured fentanyl (IMF), fentanyl analogs, and heroin use. Thus, diluting the previous progress made by organizations such as the Centers for Disease Control and Prevention (CDC), the National Institute on Drug Abuse (NIDA), and the FDA. As a result, OUD continues to plague individuals, their families, and their communities.[6]

Like the disease itself, solutions related to extinguishing the opioid epidemic are multifaceted and multifarious in nature. Confronting this epidemic begins with addressing the social stigma of SUDs, increasing patient access to treatment, and ensuring provider comfort with prescribing treatment. Enlisting the help of communities through education on proper storage and disposal of opioids, as well as training on the use of the rescue medication naloxone[7] will be essential in reducing opioid-related deaths. These interventions will be costly, but they are needed to mitigate the cost of the ongoing crisis.

① The council of economic advisers, an agency to the executive office of the president estimates the financial impact of the opioid crises (both fatality- and non-fatality–related costs) to have totaled $504 billion in 2015, a figure which accounts for approximately 2.8% of the gross domestic product (GDP) that year.[8]

Epidemiology

Despite the focus on prescription opiates, the opioid issue continues to worsen. Between 1999 and 2019, the number of overdose deaths in the United States more than quadrupled. ② Opioids accounted for over 70% of all overdose deaths in 2019 and the CDC now estimates each day at least 136 people in the United States die from an opioid overdose.[9,10] These overdoses often involve poly-substance use making it difficult to interpret and classify mortality data. Over the last 20 years, the United States has seen three different waves of opioid overdose-related deaths. The first wave started in 1999 with prescription opioids (eg, natural opioids, semi-synthetic opioids, and methadone) and continued to rise as the second wave began in 2010 marked by a substantial increase in heroin overdoses. In 2013, a third wave created an exponential rise in synthetic opioid overdoses predominantly driven by IMF compounds in cocaine, heroin, and counterfeit pharmaceuticals.[9,10]

SUD is associated with comorbidities such as cardiovascular disease, stroke, cancer, lung disease, hepatitis, and infection with the human immunodeficiency virus. These healthcare issues occur without regard to the amount or frequency of substance use by an individual. The interplay between mental health and co-occurring SUD has yet to be fully elucidated. However, the National Survey of Drug Use and Health (NSDUH)[11] indicates an association between the two, with 397,000 adolescents aged 12 to 17 reporting major depressive episodes plus SUD. Along with 9.5 million reporting having both a mental illness and SUD. The impact of this disease combination is known to further inhibit functional ability, reduce treatment success rates, increase risk of homelessness, suicidality, incarceration, morbidity, mortality, and healthcare costs when compared to individuals with a single diagnosis. While current guidelines support addressing both disorders congruently, only 1.3% of adolescents with SUD and major depressive disorder (MDD) and 7.8% of adults with SUD and acute mental health issues received concomitant treatment in 2019.[11]

The Opioid Epidemic

③ Opioid prescribing in the United States steadily increased beginning in 2006 and peaked in 2012 with 255 million prescriptions dispensed annually. Between 2012 and 2019 the rate of opioid prescribing was nearly cut in half going from 81.3 prescriptions per 100 people to 46.7 per 100 in 2019.[12] However, in 2017 over 17% of the US population still had at least one opioid prescription filled. The greater than 19% decrease in prescribing may be attributable to a combination of factors including increased regulatory oversight, enhanced awareness of opioid-related risks, educational initiatives, and new legislative efforts to improve the prescribing and dispensing of controlled substances.

A large contributor to oversight improvement came with the implementation of statewide prescription drug monitoring programs (PDMPs), which are now operational in 49 of 50 states.[13] The PDMPs are electronic systems used for tracking controlled substance prescriptions with the intent to prevent diversion (eg, patients obtaining opioids from multiple providers) and improving patient safety, while still maintaining access.[14] Pharmacies are required to report dispensing information routinely to the program in the states that participate and over 40 states also require healthcare practitioners to access this database prior to prescribing a controlled substance. Specific requirements vary by state; however, interstate communication between programs has also become common. In an effort to optimize the use of PDMPs, some states have allowed incorporation of the PDMPs into the electronic health record (EHR) systems, decreased barriers to the registration process, and the ability for prescribers to assign delegates to review the PDMP under their license.[14]

Another measure focused on promoting opioid safety and reducing related harms (eg, OUD, overdose), included the CDC's 2016 publication of a Guideline for Prescribing Opioids for Chronic Pain.[15] This document provides recommendations for primary care physicians treating adults with chronic non-malignant pain in the outpatient setting (eg, excluding malignant pain, palliative care, and end-of life care). This guideline intended to (1) improve safety and effectiveness of long-term opioid therapy and pain treatment, (2) reduce the risks associated with opioid therapy, and (3) improve communication. The publication outlines three major areas of clinical consideration: (1) determining when to initiate or continue opioids for chronic pain; (2) opioid selection, dosage, duration, follow-up, and discontinuation; (3) assessing risk and addressing harms of opioid use (see Chapter 78, Table 85-1).[15] While this guidance was originally labeled as "voluntary," many states, organizations, and third-party payers have adopted them as their foundation for policy development and legislative change related to opioid prescribing.

TABLE 85-1

Differences Between the Medications Used to Treat OUD

	Methadone	**Extended-Release Injectable Naltrexone (XR-NTX)**	**Buprenorphine**
Pharmacology in OUD	Full opioid agonist at mu-opioid receptor with long half-life to allow for once daily dosing for OUD	Antagonist at mu-opioid receptor (*note:* does not provide analgesia)	Partial agonist at mu-opioid receptor with long half-life (up to 36 hours via sublingual administration); blocks intoxicating effects of other opioids
Phase of treatment in OUD; effect	Medically supervised withdrawal, maintenance; reduces or eliminates withdrawal symptoms and cravings to use opioids, blocks or blunts the effects of illicit opioids	Prevention of relapse to opioid dependence following medically supervised withdrawal; reduces or eliminates cravings to use opioids and blunts or blocks the effects of opioids	Medically supervised withdrawal, maintenance; reduces or eliminates withdrawal symptoms and cravings to use opioids and blocks or blunts the effects of opioids
Route of administration	Provided orally once daily: Commonly given as liquid concentrate in treatment programs, but current guidelines also allow use of solid oral-dosage forms.	IM extended-release (depot naltrexone)	Sublingual, buccal tablet, buccal film
		(*note:* oral not as effective and its use is not common in the treatment of OUD due to insufficient evidence of efficacy and poor medication adherence)	Other routes of administration available after meeting specific criteria: subdermal implant, subcutaneous extended-release injection
Restrictions for prescribing each product	CII; patient must meet Federal Opioid-Treatment Program standards; can be used in hospital settings for OUD treatment	Not a controlled substance but requires a prescription. All naltrexone products can be prescribed by general practitioners and in OUD treatment	CIII; requires waiver to prescribe outside of a treatment program. Prescribers will receive a separate DEA number with a “X” upon meeting requirements of DATA 2000. They may prescribe for up to 275 individuals. To confirm practitioner verification: https://www.samhsa.gov/bupe/lookup-form
			Implant: Prescribers must be certified in buprenorphine REMS program to insert/remove implants.
			Subcutaneous: Healthcare settings and pharmacies must be certified in the Sublocade REMS program and the medication is only dispensed directly to a provider for administration.
Patients that are commonly considered for this type of therapy	Patients with OUD; physically dependent on opioids and meet federal OTP admission criteria	Patients with OUD; those who are abstinent from short-acting opioids for 7-10 days and long-acting opioids 10-14 days	Patients with OUD; physically dependent on opioids
Major side	Constipation, vomiting, dizziness,	Injection site pain and	Constipation, vomiting, dizziness, sedation, insomnia,

effects	sedation, QTc prolongation, respiratory depression (risk is highest during methadone initiation, dose titration or with concurrent benzodiazepines or alcohol use)	tenderness, risk of injection site induration, toothache, LFT elevation, insomnia, nasopharyngitis	blurred vision, respiratory depression (highest risk with concurrent use of CNS depressants including benzodiazepines); sublingual buprenorphine/naloxone sublingual and buccal film: oral hypoesthesia, oral mucosal erythema, glossodynia

CII, Schedule II Prescription; CIII, Schedule III Prescription; Federal Drug Addiction Treatment Act (DATA 2000); IM, Intramuscular; LFT, Liver Function Test.

Data from Reference 5.

Implementation inconsistencies surrounding the application of these recommendations in clinical practice has remained a point of controversy. Examples of these inconsistencies include reports of applying the guidelines to patients outside of the primary care setting (eg, patients with cancer, sickle cell disease, or recent surgery), imposing opioid prescribing limitations (eg, quantity, dosage, or duration), and tapering or discontinuing opioids without patient involvement, or adequate preparation.[16] In response to a consensus panel which outlined these challenges, the CDC issued clarification reiterating the importance of implementing the guidelines as they were intended and stressed that treatment be individualized to each patient.[17]

The FDA also launched a broad campaign in partnership with the Department of Health and Human Services (HHS), the National Academy of Medicine (NAM), and the National Institute of Health (NIH) to develop a systematic framework for the review of opioid medications that addresses their potential public health consequences (eg, long-term risk of addiction, diversion risk, and adverse effect profiles), and to expedite the approval pipeline for non-opioid analgesics and use deterrent formulations.[18] Several opioids with use-deterrent labeling and formulations have come to market since, which are designed to make it more difficult to administer the product via intravenous injection, nasal snorting, or chewing. Unfortunately, despite preliminary enthusiasm, conflicting evidence exists regarding the ability of these formulations to substantially reduce opioid use, OUD, overdose or death.[19] Further post-marketing analysis of these agents will add to the current body of evidence in determining the impact of these formulations on adverse events. Another measure to reduce opioid-related deaths by the FDA was the expansion of boxed warnings on benzodiazepines, opioid analgesics, and opioid-containing cough medicines notifying patients and their caregivers of the increased risk associated when opioids and benzodiazepines are taken concurrently.[20]

In 2018, the Risk Evaluation and Mitigation Strategy (REMS) program was expanded to include both short-acting and long-acting opioid formulations. Included with this was a requirement that training be available to all healthcare practitioners involved in pain management. The Opioid REMS Education Blueprint for Health Care Providers delivers education on pain assessment and management strategies for providers managing acute or chronic pain in the primary care setting to reduce inappropriate prescribing and adverse outcomes, while continuing to maintain access to pain medications.[21] For those healthcare practitioners still in training, the Association of American Medical Colleges continues to advance educational content related to pain assessment and management, SUDs, and responsible opioid prescribing.[22]

In 2018, the Substance Use Disorder Prevention That Promotes Opioid Recovery and Treatment (SUPPORT) for Patient and Communities Act[23] enacted to focus on prevention, treatment, recovery, and enforcement to help in the fight the opioid epidemic. This bill has many policy changes but major policy changes include the following:

- Remove restrictions on medications used for the treatment of OUD and expanding prescribing rights of these agents to select physician extenders.
- Direct Center for Medicare and Medicaid Services (CMS) to look for further options in providing telehealth services for SUDs for Medicaid and Medicare patients.
- Expand existing programs allowing more first responders to carry and use naloxone.
- Allow more federal agencies to pursue expanded research projects related to pain, substance use, and risk for addiction.
- Adjust Medicare and Medicaid processes to limit overprescribing of opioids and allow expansion of substance use treatments including adjusting restrictions to improve access to care.

- Authorize SAMHSA[24] grant programs for “Comprehensive Opioid Recovery Centers” for communities.
- Improve initiatives for education and awareness for healthcare providers on proper pain treatment.
- Improve coordination between federal agencies to test, detect, and stop substances often used at the border.
- Increase penalties for medication manufacturers and distributers related to overprescribing of opioid.
- Create incentive programs for students to pursue a career in the SUD treatment field.

Since 2018, several additional bills introduced to congress have focus on reducing barriers to the prescribing and dispensing of buprenorphine for the treatment of OUD. Accompanying these is a proposal for a national education campaign encouraging practitioners to integrate SUD treatment into practice.[25]

Etiology

Overall, the true etiology behind OUD is still unknown, as there is no way to predict why some individuals exposed to an opioid develop an OUD, while others may not. In general, it is felt that there needs to be a triad of the right patient, with the right genetic risk factors, being exposed to the right substances in order for an OUD to occur.

④ The high bioavailability, near immediate onset of action, and increased potency of IMF and its respective analogs is thought to play a causal role in overdose fatalities.[10] This postulation is affirmed by the 1040% increase in synthetic-opioid–related deaths observed from 2013 to 2019. Death rates related to prescription opioids, and heroin correspondingly have continued to rise in the presence of synthetic opioids. These combined upward trends imply that medication-related overdoses are continuing to intensify across the United States.[26]

Pathophysiology

⑤ Understanding of OUD pathophysiology is growing and, like with other SUDs, focuses around the reward center and mechanism in the brain. Substances or activities that release dopamine (DA) in the nucleus accumbens (NAc) have been clearly linked to disordered use. The current understanding is that the rapid release of DA following an opioid reaches the NAc to stimulate D1 receptors which in turn activate cyclic AMP (cAMP). This leads to the downstream effects such as euphoria and pleasure. This feeling conditions the person to associate using the substance and their surrounding environment and situation with the euphoric and pleasurable sensations. Receptors for *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) in the synapse are also conditioned by the DA release to increase glutamate signaling. These changes further modify the interconnected neural loops that lead to habit formation and disordered response to opioids. While DA and glutamate are direct signals in this system, emerging evidence seems to implicate indirect signaling via γ-aminobutyric acid (GABA), serotonin, acetylcholine, endogenous opioids, and endogenous cannabinoid compounds.[27]

Clinical Presentation

CLINICAL PRESENTATION: Acute Opioid Withdrawal and Intoxication

See Chapter e84, "Introduction to Substance Use Disorders" for complete *DSM-5* diagnostic criteria.

General

- Opioid withdrawal presents with similar signs and symptoms across the agents in the class.
- Onset, duration, and severity of withdrawal may differ depending on the opioid agent, chronicity of use, and dosage consumed.
- Onset of the acute phase of withdrawal ranges from 8 to 24 hours for short-acting opioids and 36 to 72 hours for long-acting opioids.
- The duration of withdrawal ranges from days to weeks for short-acting and long-acting opioids, respectively.
- Similarly, duration and severity of opioid intoxication is dependent on the agent, dosage, and frequency of use.

Symptoms

- Opioid intoxication: euphoria, dysphoria, apathy, lethargy, somnolence, and impaired motor skills. Individual agents may also have idiosyncratic presentations (eg, seizures with tramadol, QTc prolongation with methadone).
- Opioid withdrawal: insomnia, muscle or bone aches, abdominal cramps, vomiting, diarrhea, and anxiety or agitation. The Clinical Opiate Withdrawal Scale (COWS) or the Objective Opioid Withdrawal Scale (OOWS) are clinician-rated assessment tools used to trend the severity of opioid withdrawal symptoms and medication efficacy.

Signs

- Opioid intoxication: miotic pupils, drooping eyelids, scratching due to histamine release, decreased respiratory drive, pulmonary edema, loss of consciousness, and death.
- Opioid withdrawal: tachycardia, hypertension, hyperthermia, abnormally heightened reflexes, lacrimation, increased respiratory rate, restlessness, tremor, nausea/vomiting, diarrhea, irritability/anxiety, rhinorrhea, yawning, insomnia, dilated pupils, gooseflesh, and perspiration.

Laboratory Tests

- A comprehensive metabolic panel, complete blood count, urine toxicology screen, physical exam, electrocardiogram (EKG), infectious disease, and pregnancy screening will help guide medication selection for management of withdrawal symptoms and identification of potential medications for OUD treatment.
- For suspected opioid intoxication, blood gas, pulse oximetry, and capnography assist in monitoring for opioid-induced respiratory depression and can be used as appropriate.
- Abnormal findings may require further evaluation or referral.

Management

- To avoid needless suffering during opioid withdrawal, clinicians should attempt to manage patients in discomfort with supportive therapies.
- Patients presenting with acute opioid intoxication may require naloxone administered intermittently or in more severe cases as an intravenous infusion.

Data from References 28,29,31,32.

After repeated exposure to opioids, the nervous system adapts by creating a level of tolerance. When this repeated exposure is removed a hyperexcitable state results. Opioid withdrawal presents with similar signs and symptoms no matter the agent(s) used. Onset, duration, and severity of withdrawal may differ depending on the pharmacokinetics of the opioid agent, chronicity of use, and dosage consumed. Opioid withdrawal itself is not life threatening; however, consequences of withdrawal can be significant. Patients can experience uncontrolled pain, miscarriages, pre-mature delivery, and increased risk of suicide due to psychological distress. To avoid needless suffering during the withdrawal period supportive therapies (eg, clonidine, buprenorphine) can be implemented as appropriate to mitigate severity of discomfort. To assess withdrawal severity several validated assessment tools are available (eg, COWS, OOWS). Frequent reassessment will be prudent, as the onset, duration, and peak effects of withdrawal are dependent on the substance involved. Typically, withdrawal symptoms begin within 8 to 24 hours for opioids with a short half-life (eg, heroin), and can last up to 7 to 10 days. For agents with a long half-life (eg, methadone), symptoms can begin as early as 24 hours following the last dose but takes up to 96 hours to peak with gradual reduction of symptoms over 2 weeks or longer. The post-acute phase of withdrawal can last for weeks, months, or even longer leading to symptoms such as opioid craving and a negative affect including symptoms such as fear and irritability. It is also important to remember patients who have withdrawn from opioids will have a reduced opioid tolerance that could increase the risk of opioid overdose.[30]

Methadone

In 2014, methadone accounted for one in four prescription opioid-related deaths despite only accounting for 1% of all opioids prescribed.[31] Methadone has pharmacologic properties that are unique among opioids, and a lack of knowledge by practitioners and patients regarding these unique properties is thought to contribute to methadone-related deaths. Methadone's elimination half-life (15-60 hours; some reports as long as 120 hours) is longer than its duration of analgesic action (4-8 hours) and its full analgesic effect is usually not achieved for 3 to 5 days.[32] Doses should not be increased more frequently than every 5 to 7 days according to recent guidelines.[32] Fatal errors have been reported during conversion from other opioid agonists to methadone, as it has wide variability in equianalgesic dosing compared to other opioids. Therefore, vigilance is necessary during treatment initiation, during conversion between opioids, and during dose adjustments. Medications administered concomitantly with methadone should be evaluated for potential interactions, as methadone has many. Due to its association with prolongation of the QTc interval (in the most severe cases leading to torsades de pointes) it is prudent to monitor a patient's ECG prior to initiation and after significant dose adjustments of methadone.

Heroin

Heroin, also known as diacetylmorphine, is a serious threat to the United States and its use has increased since 2007. Since 2016 the number of heroin-related deaths has trended down, but in 2019, an estimated 14,019 Americans died from heroin-related overdoses. It remains to be seen if this is a temporary plateauing of annual deaths or the beginning of a more prolonged decrease. Overdose deaths involving co-ingestion of psychostimulants (primarily methamphetamine or derivatives) and opioids has continued to increase since 2016, which may also be contributing to the reduced mortality.[28]

The main factors associated with increases in heroin use are increased availability, low cost, and increased purity.[28,29] The DEA expects that high-purity heroin, commonly referred to as white powder heroin, will continue to be available in the United States. Now exacerbating the overdose deaths is heroin laced or adulterated with fentanyl and related derivatives that are 50 to 100 times more potent than heroin. There are conflicting opinions about whether policy changes implemented to reduce nonmedical prescription opioid use had unintended consequences by increasing the use of heroin in the United States. Opioid prescribing policies could help decrease heroin overdose deaths.[33]

Heroin is hydrolyzed to 6-acetyl morphine and subsequently morphine. It acts as an agonist at opioid receptors including the mu, kappa, and delta receptors. Administration can occur via multiple routes including intranasal, intravenous, subcutaneous, intramuscular routes, or smoking. Heroin is very lipophilic and crosses the blood brain barrier (BBB) quickly which leads to very rapid absorption and arrival to the site of action; 5 to 10 minutes when administered subcutaneously, 3 to 5 minutes intranasally and intramuscularly, and <1 minute when administered intravenously.[34] Although the initial half-life is approximately 8 hours, the ultimate duration of effect from heroin is dependent on the person's history with the medication and how it is administered. The oral route is typically not preferred due to first pass metabolism to morphine which leads to less rapid onset of action.[34]

As tolerance develops, the half-life decreases leading to earlier withdrawal symptoms including dilated pupils, hostility, sweating, vomiting, diarrhea, yawning, and piloerection. Those that use heroin increase doses and rates of administration to avoid these withdrawal symptoms, which increases their overdose risk. Symptoms of heroin use include sedation, decreased respiration, apnea, cardiac arrest, and death without medical treatment such as administration of naloxone.[35] Testing for heroin in urine, blood, or other biological samples is difficult due to the very short half-life of intact heroin

(2-6 minutes). Unfortunately, the next metabolite, 6-acetylmorphine (6-AM) is only present in urine and blood for approximately 6 to 25 minutes before it is hydrolyzed to morphine and other metabolites. As morphine and other metabolites can be detected on a urine screen after heroin use, as well as after use of certain prescription opioids, results from urine screens are often misinterpreted and require confirmatory secondary testing and a thorough clinical evaluation.[35,36]

Fentanyl

Fentanyl is a synthetic short-acting opioid analgesic, that is 50 to 100 times more potent than morphine and is approved for managing acute or chronic pain, as well as pain associated with advanced cancer. Although pharmaceutical fentanyl can be diverted for use, most cases of fentanyl-related morbidity and mortality have been linked to illicitly manufactured fentanyl and fentanyl analogs (IMF). Since 2015, there have been almost yearly CDC public health fentanyl advisories including a public health advisory regarding increased fentanyl-related overdose deaths, a warning that fentanyl was found in counterfeit pills in the United States, and a report regarding the rise in fentanyl analogs contributing to opioid overdose deaths.[37]

Generally, the IMF products are sold via illicit markets, with individuals seeking them out for their heroin-like effect. Additionally these illegal products are often mixed with heroin and cocaine and marketed as an oral opioid or benzodiazepine.[37] Deaths from counterfeit opioids and benzodiazepine pills laced with fentanyl have been reported and are believed to be contributing to the increased overdose rates. A CDC analysis from 31 states and Washington DC from 2015 to 2016 showed that overdose death rates increased by 21.5%, and the death rates from synthetic opioids (presumed to be IMF) more than doubled. The death rates for heroin, cocaine, and psychostimulants also increased by 19.5%, 52.4%, and 33.3%, respectively, and the CDC attributes a portion of rate increases to the presence of IMF in the respective products.[38]

Other Opioid-Related Substances

Intoxication from the OTC cough suppressant, dextromethorphan[39] occurs from consuming large doses of liquid cough syrup that is known as "robodosing" or "robotripping" and those who use the cough syrup in this manner are sometimes called "syrup heads."[39] Additionally, "skittles" is a term used to describe use of other cough and cold remedies because they look similar to the popular candy. As dextromethorphan is an opioid analog, large doses can create a depressant and sometimes profound hallucinogenic effect, and since it is available OTC it is easily procured by adolescents.[39]

Loperamide is also another dangerous example of OTC medication that is often used. Pharmacologically this medication acts as an intestinal mu-opioid agonist that works locally for the short-term treatment of diarrhea. When used in this fashion, at normal recommended doses, it does not cross the blood brain barrier and will not have any CNS effects.[40] When taken at high doses, or with concomitant medications that inhibit the P-glycoprotein efflux transporter, CNS effects can be seen.

Treatment

Desired Outcomes

⑥ As with any use disorder the desired treatment outcomes for OUD are reduction in use of the substance, reduction in substance-induced disorders, and prevention of death from the substance. The course and prognosis of OUD is variable. Getting patients to stop misusing can be quite difficult, and many patients return to opioid use even after treatment. It has been reported that as many as 40% to 60% of treated patients with a SUD will relapse within 1 year.[41] However, many patients can achieve recovery with proper treatment and continued care in counseling programs or 12-step programs such as Narcotics Anonymous. It is important to note that the treatment of OUD is a chronic condition that needs proper medical treatment and appropriate follow-up, as relapses are common. Therefore, providing medication for long-term maintenance decreases the risk of an accidental overdose or full relapse into opioid use. Continued patient education and support is vital to helping patients continue their set treatment goals.

Pharmacologic Therapy

A variety of treatment regimens are used for patients during the acute opioid withdrawal phase. Initiating buprenorphine in the emergency room for patients who present with opioid withdrawal symptoms has become a treatment option. The reader is directed to Cisewski et al.[42] for a detailed review outlining the process for establishing this stepwise treatment practice.

Methadone has also been used as a long-acting opioid option to aid in treatment of withdrawal symptoms.[43] The use of clonidine, an alpha-2 agonist, has commonly been used to attenuate withdrawal symptoms such as anxiety, tachycardia, hypertension, chills, and piloerection. Patients must be monitored for side effects including hypotension, dizziness, and sedation following administration of clonidine.[43] Lofexidine, also an alpha-2 agonist, has been found to be more effective than placebo in managing withdrawal from methadone or heroin and has demonstrated a better safety profile compared to clonidine.[43,44] Replacement of fluids due to losses from perspiration, vomiting, and diarrhea is crucial during withdrawal and other patient-specific supportive care measures should be provided until the patient stabilizes. Ongoing follow-up is important since post-acute withdrawal can continue for an extended period of time. This can increase risk of relapse and heighten the risk of overdose.

⑦ Although OUD can range from mild to severe, it often requires continual care including patient-centered care involving mental health services, medical services, counseling, and the use of medications for treatment. The three FDA-approved medications used in OUD include methadone, buprenorphine, and naltrexone that work by blunting or blocking the effects of opioids and reducing or eliminating craving. All three agents have demonstrated superiority over no treatment in reducing opioid use,[30,45,46] and methadone and buprenorphine decrease the risk of overdose deaths. All of these medications have unique characteristics that healthcare providers must be aware of, including differences in mechanism of action, routes of administration, and side effects. It is also important to understand in what phase of treatment each of these agents is used, and the regulations associated with their use (Table 85-1).

Methadone

Methadone is a mu-opioid agonist that suppresses withdrawal symptoms and controls the craving for opioids in maintenance therapy. Controlled trials have shown that methadone use in patients with OUD is superior to placebo and has demonstrated a reduction of mortality, incidence of HIV infection, and criminality.[10] Recommended once daily dosing of methadone on the first day of treatment for patients tolerant to opioids can range from 10 to 30 mg, depending on the patient's use pattern. The patient should be reassessed in 2 to 4 hours after this initial dose for signs of sedation or symptoms of withdrawal. Additional monitoring and/or treatment can continue if needed during the first day based on the initial response. Although rare, if the dose does exceed 30 mg on the first day of treatment, monitoring for over-sedation should occur for multiple days.[30] In patients who are older than 60 years of age, have identified medication interactions, or have other medical conditions that can lead to increased risk of hypoxia, it is recommended to limit the initial maximum methadone daily dosing to 10 to 20 mg. Dosing ranges for stabilization that eliminate withdrawal and craving, block euphoric effects of illicit opioids, and that are not normally associated with sedation are commonly between 60 and 120 mg administered once a day for most patients but this can vary considerably.[30] Titrating the methadone dose must be individualized and based on a full assessment of the patient. Due to its long half-life and extended time to reach steady state, daily dose adjustments should not occur, as they can result in over-sedation and possible increased risk of toxicity. It is recommended that dose adjustments of 5 to 10 mg should occur gradually, with each adjustment occurring no sooner than every 4 to 7 days based on clinical response. This will allow for achievement of steady state and account for the other numerous factors that can impact serum levels.[30,32] Concerns with methadone include medication interactions due to the variety of concomitant cytochrome P450 (CYP 450) inducers that can reduce methadone levels. Concomitant use of alcohol or benzodiazepines can lead to overdose and use should be assessed. Additionally, the risk of QT prolongation is increased with methadone use, especially when given with other medications that also prolong the QT interval. The use of methadone for the treatment of OUD is only approved through the opioid treatment programs controlled by the DEA and SAMHSA. However, methadone for the treatment of OUD may be provided to patients during a hospital admission for the treatment of other health conditions such as pain. Patients who as part of an opioid treatment program most often receive it on a daily basis with daily onsite administration; however, some patients are allowed to take doses at home if they meet a list of criteria set by federal regulations.[47]

Naltrexone

Naltrexone is a mu-opioid antagonist available as both an oral tablet and an extended-release injectable formulation for the treatment of OUD.[48,49] It is important to note that while the oral tablet has not been found to be any more effective than placebo in a meta-analysis of 13 studies,[50] naltrexone reduces opioid use and retained treatment participation compared to placebo.[45]

To use the oral formulation, patients need to have confirmation of being opioid free for 7 to 10 days as assessed through the use of a urine drug screen or naloxone challenge. The initial dose given is 25 mg once daily and if no symptoms of withdrawal are demonstrated, this can be increased to the target dose of 50 mg once daily.[48] Extended-release injectable naltrexone (Vivitrol ®) is FDA-approved for use following opioid detoxification to help prevent relapse.[49] It is important to review all medication-associated adverse effects with patients, including education on the length of time naltrexone is active and their vulnerability to opioid effects at the end of a dosing interval, after a missed dose, or with treatment discontinuation. Patients should be informed to contact their provider if any excessive swelling, bruising, or pruritus occurs at the injection site since this could be a sign of improper subcutaneous injection and may require medical treatment. The REMS information highlights the risk of severe injection site reactions and provides education for healthcare providers including proper techniques to reduce severe injection site reactions as well as important counseling points to use with patients to identify any signs or symptoms of injection site reactions.[49] Naltrexone is not a controlled substance and is not included in the opioid treatment program regulations, but it does require a prescription and a monthly medical office visit. The use of extended-release injectable naltrexone should be part of a comprehensive patient program that includes psychological counseling and support.

Buprenorphine

Buprenorphine is a partial mu-receptor agonist that is very lipophilic and available as buprenorphine alone or in combination with naloxone. These products have been shown in numerous studies and clinical trials to be effective treatment options for OUD both in reducing opioid use and treatment retention.[47] It is now recommended by the Best Practice Guidelines (TIP 63) expert panel[30] and the Department of Veterans Affairs Guidelines[51] that FDA-approved buprenorphine formulations should be offered to patients with OUD who are appropriate candidates. As buprenorphine is a partial mu-receptor agonist, it does provide some intrinsic pain control. Additionally, due to the partial agonist activity, it also has a ceiling effect for respiratory depression, except when combined with CNS depressants such as benzodiazepines or alcohol, where there have been reports of increased risk of respiratory depression. Furthermore, due to the partial agonist activity, any full agonist activity will be blunted, such as that provided from heroin or other opioids. This effect will be prolonged due to the long half-life and prolonged receptor dissociation properties of buprenorphine.[52] At the time of this writing there are buprenorphine/naloxone sublingual tablets and films, buprenorphine/naloxone buccal films, buprenorphine implants, buprenorphine tablets, and a buprenorphine extended-release injection.[52] Newer products have greater bioavailability compared to previous products, making product selection and conversion between buprenorphine products an important consideration for healthcare providers (Tables 85-2 and 85-3).[52,53]

TABLE 85-2

Oral Buprenorphine Products Used in Treatment of Opioid Use Disorder

	Buprenorphine Tablet	**Suboxone SL Tablet**	**Zubsolv SL Tablet**	**Suboxone SL Film**	**Bunavail Buccal Film**
Strengths of products commercially available/Routes of Administration	**Sublingual Tablet:** 2 mg 8 mg	**Sublingual Tablet:** 2/0.5 mg 8/2 mg	**Sublingual Tablet:** 0.7/0.18 mg 1.4/0.36 mg 2.9/0.71 mg 5.7/1.4 mg 8.6/2.1 mg 11.4/2.9 mg	**Sublingual or Buccal Film:** 2-0.5 mg 4-1 mg 8-2 mg 12-3 mg	**Buccal Film:** 2.1-0.3 mg 4.2-0.7 mg 6.3-1 mg
Recommended Once-Daily Target Maintenance Dose and Dosing Ranges	**Target Maintenance Dose:** 16 mg **Dosing Range:** 4-24 mg[a]	**Target Maintenance Dose:** 16/4 mg **Dosing Range:** 4/1 to 24/6 mg[a]	**Target Maintenance Dose:** 11.4/2.9 mg **Dosing Range:** 2.9/0.71 to 17.2/4.2 mg[b]	**Target Maintenance Dose:** 16/4 mg **Dosing Range:** 4/1 to 24/6 mg[a]	**Target Maintenance Dose:** 8.4/1.4 mg **Dosing Range:** 2.1/0.3 to 12.6/2.1 mg

SL, sublingual

[a] Doses higher than 24/6 mg do not offer any further benefit.

[b] Doses higher than 17.2/4.2 mg do not offer any added benefit.

Note: Refer to individual product dosing information when switching formulations due to possible bioequivalence variability. Monitoring is recommended following a switch in products due to possible variation in response to different formulations.

Data from References 32,54–57,63,64.

TABLE 85-3

Patient Education Points for Buprenorphine Treatment

Prior to starting buprenorphine therapy and repeated at induction
• **Communication with prescriber:** Tell your prescribers all medications including over-the-counter (OTC), herbal, creams, injections, inhalants, street medications, etc. that you are currently taking. This is important so your healthcare team is aware of what is in your body and if there are any chances of a dangerous medication interactions. Additionally, it is important to tell all of your prescriber and healthcare team you are taking buprenorphine, especially if you are being treated for pain. • **Goals of therapy:** The goal of your first week of treatment is to improve withdrawal symptoms without causing any over-sedation (making you too tired or feeling over medicated). It is important to notify your prescriber if you are feeling overly tired/sedated or euphoric within 1 to 4 hours of your dose. Dose adjustments might occur initially and it will take a little time for the buprenorphine to become stable in your system. The goals of therapy include finding the right dose to eliminate withdrawal, decrease or even eliminate cravings for opioids, and block the effects of other opioids without

severe adverse medication effects.

- **Product use:**
    - Buprenorphine products (tablets, sublingual film, and buccal film) are not equivalent. If you have to transition to a new buprenorphine product, a dose adjustment might be required.
    - Take your dose at regular intervals and only as prescribed.
    - If you miss a dose, take the dose as soon as possible. If it is almost time for the next dose, do not double your dose, take only the dose that is prescribed.
    - Leave medication in packaging until you are ready to use.
    - Do not swallow sublingual tablets or film. This can lead to a decreased effect of buprenorphine that can lead to withdrawal symptoms.
        - Sublingual tablets:
            1. Place tablets under tongue and allow the tablet to fully dissolve which can take several minutes
            2. If your dose requires multiple tablets, all tablets can be placed under the tongue at one time. If this is uncomfortable, only place two tablets under the tongue at a time.
        - Sublingual film:
            1. Drink water prior to placing the film to help the film dissolve easily
            2. Place film under the tongue, to the left or right of the center of the tongue, and allow to completely dissolve
            3. If you are prescribed 2 films at a time, place the second film on the opposite side of the tongue. Do not allow the films to touch.
            4. If you are prescribed more than 2 films at a time, wait until previous films have dissolved and repeat the process.
        - Buccal film:
            1. Wet the inside of your cheek with your tongue or rinse with water prior to placing film
            2. Hold the film by the edges with two fingers and place on inside of cheek until fully dissolved that can take up to 30 minutes
            3. If you are prescribed two films, place the second film inside the opposite cheek
            4. Do not adjust the film placement or touch the film, do not chew or swallow the film
            5. Do not drink or eat until the film has completely dissolved
- **Common adverse medication effects:** These do not happen all of the time and do not happen to everyone. If you are experiencing any of these adverse medication effects please tell your healthcare team immediately. Do not stop taking buprenorphine without first speaking to your prescriber. The most common adverse medication effects that have been experienced include headache, nausea, constipation, abdominal pain, insomnia, sweating, and a possible feeling of weakness or lack of energy.
- **Precautions and warnings**:
    - Using benzodiazepines or alcohol while taking buprenorphine is very dangerous and can lead to increased risk of overdose and possibly death.
    - Using tobacco products prior to using buprenorphine has been shown to decrease the absorption of buprenorphine decreasing its effectiveness.
    - Long-term buprenorphine maintenance is recommended in many cases. If you stop buprenorphine, there is a high risk of overdose if you return to misusing opioids.
    - Buprenorphine is an opioid that can cause physical dependence. Do not stop taking buprenorphine without consulting your prescriber. If you stop buprenorphine abruptly, you could experience withdrawal symptoms.
    - All medications, including buprenorphine, should be stored in a secure area, preferably in a locked cabinet or safe. It is important to keep medication away from children.
    - It is recommended that you do not drive, operate heavy machinery, or perform any dangerous activities until you are fully aware of how this medication affects you.
    - If you feel you have taken too much buprenorphine, you will need emergency medical attention immediately. Some possible signs include dizziness, confusion, unsteady or faint, slowed reflexes, or breathing slower.
    - Do not inject these products. Serious life-threatening infections could occur. Additionally, serious withdrawal reactions can also occur upon injecting many of these buprenorphine products.
- **Pregnancy:** It is very important to inform your healthcare team if you become pregnant.
- **Counseling options:** Recovery resources and counseling resources are available for you and your family. We can give you further information on this when you are ready.

Maintenance

- **Adherence assessment**: If any discrepancies arise, initiate discussion to identify reasons for discrepancies
    - Complete pill/film count
    - Review Prescription Drug Monitoring Program
    - Confirm current buprenorphine dose
    - Review results of urine drug analysis
- **Treatment assessment and counseling:**
    - Review treatment goals and assess progress
    - Review and assess benefits and risks of continuing buprenorphine treatment
    - Discuss participation in counseling or encourage counseling if not receiving counseling

Data from References 30,43,58.

⑧ Patients who achieve clinical stability have longer acting options that may improve adherence and improve quality of life (Table 85-3). Buprenorphine is a Schedule III controlled substance with specific prescribing restrictions. Table 85-1 outlines some of these restrictions. Recent legislation has extended regulations to allow physician assistants, nurse practitioners, clinical nurse specialists, certified nurse midwives, and certified registered nurse anesthetists to prescribe buprenorphine. This practice varies by state based on laws and regulations, therefore each state licensing board should be consulted for the most up to date laws and regulations.

Prior to prescribing buprenorphine, a full assessment including reviewing the PDMP database and a full medication review should be completed. Care should be taken to screen for medication interactions including HIV medications, benzodiazepines, CNS depressants, and CYP 450 inducers/inhibitors. Additionally, a urine drug screen, informed consent, and treatment agreement should be completed. Comprehensive patient education is very important to help improve adherence to the treatment plan and improve patient safety (Table 85-4).

TABLE 85-4

Extended-Release Products Approved by FDA for Opioid Use Disorder

Medication	Trade Name	Dose	Comments
Naltrexone Tablets	Revia	Following 7-10 day opioid-free period for short-acting opioids or 10-14 day opioid-free period for long-acting opioids: begin with dose of 25 mg daily with food. If no signs of withdrawal, increase dose to 50 mg PO daily.	• Should be part of a comprehensive treatment plan that includes psychosocial support • Although specific dosage adjustments are not available for patient with hepatic dysfunction, reports of elevated LFTs have been reported; use with caution. • Use with caution in patients with renal impairment, although data is limited, naltrexone and active metabolite are renally excreted.
Naltrexone XR Injection	Vivitrol	Following 7-10 day opioid-free period for short-acting opioids or 10-14 day opioid-free period for long-acting opioids: 380-mg IM in gluteal area alternating buttocks; every 4 weeks or once a month.	• Must be administered by a healthcare provider • Must use manufacture provided needle and assess body size of patient at each visit so proper needle size is used • Monitor injection site closely for any signs of abnormal pain and contact healthcare provider immediately if this occurs • Dose adjustment is required in mild or moderate hepatic impairment. No data available in severe

			hepatic impairment • No dose adjustments in mild renal impairment; use caution in patients with moderate-to-severe renal impairment, naltrexone and active metabolite are renally excreted

Buprenorphine	Probuphine	Four implants are inserted subdermally in the inner side of the upper arm and should remain in place for 6 months.	• Patients must meet specific criteria for use of Probuphine:
			  ○ Only indicated for patients who are opioid tolerant
			  ○ Demonstrates clinical stability on transmucosal buprenorphie with Subutex or Suboxone 8 mg/day or less (or transmucosal equivalent) for 3 months or longer without requiring supplemental dose adjustments
			• Probuphine must be inserted or removed within a facility and by a certified provider who has completed the required live training
			• It is recommended to not prescribe prn transmucosal buprenorphine products. If patient is requesting these products, reassessment is indicated
			• Moderate-to-severe hepatic impairment: use not recommended
			• Limited data in renal impairment, currently no dosage adjustments listed

Buprenorphine	Sublocade	For patients who have achieved clinical stability on equivalent of 8-24 mg of a transmucosal buprenorphine product daily.
		Available in two extended-release solutions:
		  ○ *100 mg/0.5 mL*
		  ○ *300 mg/1.5 mL*
		Directions: Inject 300 mg subcutaneously once a month in abdominal area for 2 months, then decrease dose to 100 mg once monthly in abdominal area.
			• Must be administered by a healthcare provider
			• Steady state occurs after 4-6 months; after discontinuation of detectable buprenorphine levels could occur 12 months or longer; urine and plasma concentration correlations are not known.
			• Injections must occur at least 26 days apart. Follow all manufacturers' direction for preparation and injection.
			• Do not give the injection at the belt or waistband area where pressure will occur
			• It is important to counsel the patient that there will be a small bump at the injection site that will decrease in size over the next several weeks. It is important not to rub or massage this area.
			• If needed, the most recently injected depot can be removed within the 14 days of injection under local anesthesia.
			• Doses can be adjusted back to 300 mg monthly for patients in which benefits exceed risks.
			• Examine injection site each month for evidence of tampering
			• Moderate-to-severe hepatic impairment: use not

			recommended - Limited data in renal impairment, currently no dosage adjustments listed

mg, milligram; IM, Intramuscularly; mL, milliliters.

Data from References 5,51,58,59.

When the patient presents to begin buprenorphine, it is important for the clinician to assess the patient carefully for signs of sedation or intoxication since buprenorphine should not be started under these circumstances. As the patient should be present in the beginning stages of withdrawal to start buprenorphine, a validated assessment scale, such as the Clinical Opiate Withdrawal Scale (COWS), can be used for assessment. It is recommended that treatment start with a COWS score of 12 or higher for the first dose, based on buprenorphine REMS.[30]

Medically supervised withdrawal with buprenorphine consists of an induction phase and a dose-reduction phase, followed by maintenance.[30] Best practice guidelines are periodically issued for treatment of OUDs. The TIP 40[52] (entitled “The Guideline for the Use of Buprenorphine in the Treatment of Opioid Addiction”) provides consensus- and evidence-based guidance on the use of buprenorphine and the TIP 63 provides similar guidelines as outlined below for buprenorphine treatment.[30] Induction is the first stage of buprenorphine treatment and involves helping patients begin the process of switching from the used opioid to buprenorphine. The goal of this phase is to find the minimum dose of buprenorphine at which the patient discontinues or markedly diminishes use of other opioids and experiences no withdrawal symptoms, minimal or no adverse medication effects, and no craving for the used substance. This phase is commonly initiated in the physician office when the patient is in mild to moderate withdrawal with the last dose of opioid use occurring 6 to 12 hours prior for heroin or short-acting opioids. For longer-acting opioids such as methadone, it is recommended to wait 24 to 72 hours after the last dose. Patients are typically monitored in the office at approximately 2-hour intervals after the first dose of buprenorphine with continued dose titration until the withdrawal symptoms are eliminated. Guidelines recommend weekly follow-up until the patient is stable and then monthly follow-up can be considered.[52] Although office-based induction has traditionally been recommended, home induction is an alternative growing in use.[30] The American Society of Addiction Medicine National Practice Guidelines recommends that both the patient and prescriber have prior experience with the medications used to treat OUD, in order to consider this option.[52,60]

The stabilization phase begins when a patient is experiencing no withdrawal symptoms, is experiencing minimal or no adverse medication effects, and no longer has uncontrollable cravings for opioid agonists. Buprenorphine dosage adjustments may be necessary during early stabilization, and frequent contact with the patient increases the likelihood of compliance. Ongoing psychological evaluation for mental health or psychological issues is recommended so proper medical assistance can be provided immediately if needed.[30]

Maintenance is the longest phase of treatment as this period may be indefinite and longer treatment has been associated with positive treatment outcomes.[61] During the maintenance phase, attention must be focused on the psychosocial and family issues that have been identified during the course of treatment that contribute to a patient’s OUD.[61] Other issues related to OUD that need to be addressed during maintenance treatment include, but are not limited to, psychiatric comorbidity, consequences of drug use, family support issues, structuring of time in prosocial activities, employment and financial issues, legal consequences of medication use, and the use of other substances. Ongoing monitoring will continue to include urine drug tests, and patient education regarding this aspect is important so there is understanding that this testing is used more to help them meet treatment goals and not as a tool for punishment.[30]

Naloxone

⑨ Naloxone is a key strategy in reducing opioid-related deaths,[62] as patients who are being treated for OUD, or who are not taking medications for OUD but are at high risk of returning to opioid use, are at substantial risk of overdose. It is imperative that patients and their caregivers are educated on the availability of naloxone and the proper use of this agent. Pharmacologically, naloxone hydrochloride is a competitive mu-opioid receptor antagonist that can be used in the reversal of an opioid overdose. It can be administered through a variety of routes including intravenous (IV), intramuscular (IM), subcutaneous (SQ), intraosseous, (IO), and intranasal (IN).[63] The onset of action when delivered via intravenous route can be as fast as 60 seconds, but is approximately 2 to 5 minutes when delivered IN.[63] The duration of effect is dependent upon the dose and the specific opioid naloxone is reversing. It is important for interested parties to know that if a long-acting opioid such as methadone is involved, the patient could show decompensation after initial improvement due to the long half-life of methadone and comparatively short half-life of naloxone.

The FDA has approved two devices to deliver naloxone that can be administered by nonmedical bystanders: the intramuscular autoinjector Evzio® and an intranasal delivery device, Narcan®. A third option readily available prior to these new devices, the generic injectable naloxone solution used with a mucosal atomization device, is used in the community setting, although it is not approved by the FDA. For this device, extra education is necessary on how to connect the components and then administer the 1-mg dose per nostril.[63] Table 85-5 includes more information about naloxone delivery options and counseling information.

TABLE 85-5

Delivery Options for Naloxone

	Intramuscular Injection	Auto-Injector (Evzio)	Nasal Spray (Narcan)	Intranasal Spray (Atomizer)
Description of device or what is provided	Two single use 0.4-mg/mL naloxone vials	One box 2-mg/0.4-mL prefilled auto injector that include 2 devices and a trainer devices	One box that contains two 4-mg/0.1-mL intranasal devices	2-mg/2-mL prefilled naloxone needleless syringe
	Two single use 3-mL syringe 23-25 gauge 1-1.5 in. needles			Two mucosal atomizer devices
Directions for use	Inject 1-mL intramuscularly in shoulder or thigh upon signs of opioid overdose. Call 911 immediately. May repeat once more in 2-3 minutes if inadequate response.	Apply one auto-injector to the outer thigh by depressing and holding for 5 seconds. The voice automation will direct the patient with this device. Call 911. May repeat once more in 2-3 minutes if inadequate response.	Use full contents of nasal spray in one nostril upon signs of opioid overdose. Call 911. May repeat once more in 2-3 minutes if inadequate response using the other nostril.	Spray one-half of contents of syringe into each nostril upon signs of opioid overdose. Call 911. May repeat once more in 2-3 minutes if inadequate response.

Naloxone pearls:

- Naloxone has not been shown to cause severe effects or adverse medication effects if administered to patients who are currently not taking opioids.
- Naloxone should be given if the patient is intoxicated by a combination of products since the naloxone will still work for the opioid but not for other products such as benzodiazepines or alcohol.

Naloxone counseling topics that should be covered:

- Overdose recognition, response, prevention
- Importance of seeking emergency medical care
- Proper device use and counseling of family members and caregivers
- Proper storage, shelf life. Periodically check expiration date
- Potential adverse medication effects associated with naloxone
- Availability of substance use disorder treatment program

General opioid safety counseling:

- Take medication only prescribed for you, only take prescribed doses
- Do not mix opioids with alcohol or sleeping pills
- Always store all medications in a locked and secure place
- Dispose of unused medications appropriately
- Do not use opioids/medications in seclusion. Never buy opioids/medications from unknown source
- Do not restart opioid at same dose if there is a period of abstinence. Overdose is possible due to lower tolerance

Data from References 63–65.

Inadequate response to less sensitive opioids such as buprenorphine, fentanyl, or other synthetic opioids may be seen with take-home naloxone (THN).[62,64] Higher doses of naloxone may be needed in such a scenario; therefore, it is vital that emergency services are contacted to provide ongoing care.[62,65] However, the THN products might provide time for arrival of medical professionals and/or transportation to medical facilities for more definitive treatment.

Controversy exists regarding concerns that distribution of naloxone may increase drug use, as some authors feel naloxone has contributed by "providing a safety net that encourages riskier use."[66] However, data from communities that have implemented overdose programs prior to this report have documented a decrease in overdose death rates. In fact, overdose education and naloxone distribution (OEND) programs in the community have been occurring since 1996, and this practice was embraced by the World Health Organization (WHO) guidelines which recommend that anyone who might witness an overdose have access to naloxone and proper training.[66]

As the number of opioid overdoses has continued to increase, CDC guidelines have recommended increasing use of THN. In fact, improving access has become a goal of many states through expanding those able to distribute naloxone or simplifying the process of obtaining the naloxone. Additionally, improved education of healthcare providers and the community as a whole has also been a primary goal.[67]

Opioid Use Disorder in Pregnancy

As the rates of opioid use in the United States have increased, the number of pregnant women diagnosed with OUD has increased substantially.[68] The occurrence of opioid use during pregnancy results in an increased risk of preterm labor, neonatal abstinence syndrome, and maternal mortality. The CDC reported the rate of OUDs in women at delivery has more than quadrupled between 1999 and 2014.[68] Current recommendations for a pregnant woman with an OUD requesting treatment includes methadone or buprenorphine, and behavioral interventions. Now, the safety of extended-release injectable naltrexone is still under study. For patients taking naltrexone, it is recommended that it be converted to buprenorphine or methadone during the pregnancy.[69] More specifics regarding treatment in this population can be obtained from recently released guidance documents for healthcare providers entitled "Clinical Guidance for Treating Pregnant and Parenting Women with Opioid Use Disorder and Their Infants."[69]

Key to the success of OUD treatments in this population is patient education, which should include topics such as the risks and benefits of the chosen medication. During this discussion, it is important to stress to the patient there are some disagreements on the risks associated with these medications. Now, research efforts have not linked buprenorphine or methadone use with an increased risk of birth defects and or issues with long-term neurodevelopment.[69] Other important topics to discuss with the patient include risk of neonatal abstinence syndrome and details associated with this syndrome, as well as important strategies for improving the patient's health and the pregnancy. Due to the large number of pregnant women presenting with OUDs, all healthcare providers should look for substance use behaviors in their pregnant patients, and if identified, provide a referral for therapy as quickly as possible to improve the outcome for both the mother and the baby.[69]

INTRODUCTION: BENZODIAZEPINES AND OTHER SEDATIVE-HYPNOTICS

Benzodiazepines, while not first-line treatment options, are commonly prescribed for anxiety, muscle spasms, and insomnia in a variety of practices. While their therapeutic use can be quite helpful to patients, similar to the opioids, their CNS effects can make them substances commonly used.

Epidemiology

⑩ Benzodiazepine prescribing has increased by over 65% from 1996 to 2013 and continues to climb. Overdose rates have increased over sevenfold from 2002 to 2019, the peak occurring in 2017.[28] When benzodiazepines are given concomitantly with an opioid, the combination can lead to increased CNS effects such as dizziness and sedation but also deadly respiratory depression. A cohort study that included over 2 million opioid prescriptions in one year demonstrated 80% of these were co-prescribed with a benzodiazepine and the rates of overdose deaths in this group were 10 times higher than opioid analgesics alone.[70] In 2016, the FDA announced a class wide medication labeling change for both opioids and benzodiazepines requiring both classes to include black box warning indicating that concurrent use could cause sedation, respiratory depression, coma, and death.[71] Additionally, the CDC Guidelines for prescribing opioids for chronic pain recommends avoiding concurrent benzodiazepine and opioid prescriptions whenever possible highlighting the dangers of using this combination.[15]

Etiology

Pharmacologically, the benzodiazepines increase the affinity of gamma amino butyric acid (GABA) for its receptor and augment GABA-mediated inhibitory signaling. This occurs by targeting the $GABA_A$ receptor that has multiple subunits. Activation of these subunits leads to an increase in frequency of ion channel opening that leads to an influx of chloride ions and membrane hyperpolarization.[72] Benzodiazepines vary in pharmacodynamics and pharmacokinetic properties, with additional details being found in Chapters 90 and 91.

A class of medications related to the benzodiazepines include eszopiclone, zaleplon, and zolpidem, which are prescribed for insomnia, and commonly known as the Z-hypnotics. While pharmacologically they may differ from benzodiazepines, tolerance and withdrawal have been reported with their use and they should be used with caution.[73] Additionally, this class of medication is required by the FDA to include labeling that warns of a variety of psychological and behavioral adverse medication effects that include sleep driving. Depression and suicidal thoughts have also been linked to these products, although this has been seen mainly in patients taking both sedatives and hypnotics concurrently.[73]

Pathophysiology

Benzodiazepines have been shown to cause release of dopamine in the mesolimbic region of the brain, which is a hallmark of substances that can lead to use disorders.[73] Additionally, benzodiazepines have demonstrated an ability to activate dopaminergic neurons in the ventral tegmental area through GABA_A interactions involving interneurons in the region. These two neuronal pathways within the addiction centers of the brain explain their potential for developing disordered use of this medication class. Due to their use liability, patients cannot be switched from one benzodiazepine to another in hopes of decreasing this behavior pattern. Additionally, long-term use of even therapeutic doses of these agents, can cause physical dependence and withdrawal symptoms after abrupt discontinuation, including seizures. In general, shorter-acting benzodiazepines have higher risk of use potential due to the immediate “rush” or “high” feeling. Gradual tapering (4 weeks or longer) of dosage is also associated with less withdrawal and rebound anxiety than abrupt discontinuation.[73]

Clinical Presentation

CLINICAL PRESENTATION: Benzodiazepine Intoxication and Withdrawal

General

- The intoxicated patient may be in acute distress during overdoses or when benzodiazepines are combined with alcohol.
- Patients in withdrawal may be in acute distress and should be treated with a benzodiazepine taper to prevent seizures.

Symptoms

- Symptoms of intoxication may include memory impairment, drowsiness, visual disturbances, confusion, and gastrointestinal disturbances. Patient may appear intoxicated, with slurred speech, poor coordination, swaying, and bloodshot eyes, with or without the odor of alcohol.
- Symptoms of withdrawal can include agitation and restlessness, confusion, anxiety, sleep disturbances, dizziness, flu-like symptoms, impaired memory and concentration, irritability, nausea and vomiting, nightmares, visual disturbances, convulsions, hallucinations, and psychosis.

Signs

- Hypotension or nystagmus may be observed and urinary retention may occur.
- Nervousness, sweating, trembling, hypertension, tachycardia, weakness, tremors, and seizures are examples of possible signs in acute withdrawal.

Laboratory Tests

- Qualitative testing to confirm presence of benzodiazepines is useful for diagnostic purposes, but quantitative plasma concentrations are usually not clinically useful due to the length of time required for results to be obtained at most institutions.

Treatment

Desired Outcomes

Similar to the desired outcomes for individuals misusing opioids, the overall goals of treatment are to reduce dependency, the incidence of substance-induced disorders, and death.

Non-pharmacological management as a primary treatment for benzodiazepine intoxication or withdrawal is not indicated. Rather, direct pharmacologic care of an individual intoxicated with a benzodiaepines includes the use of supportive care. For patients undergoing benzodiazepine withdrawal supportive care should be provided in combination with pharmacologic therapy.

Pharmacologic Therapy for Benzodiazepine Intoxication and Withdrawal

⑪ Symptomatic and supportive care is the standard of care for benzodiazepine intoxication. Management primarily includes support of bodily functions to allow for metabolism and excretion of the medication from the system. For individuals that use short-term withdrawal is not expected and thus flumazenil can be considered. Flumazenil reverses the intoxicating effects of benzodiazepines and Z-hypnotics by competitively inhibiting the GABA/benzodiazepine receptor complex. However, caution should be exercised as indiscriminate use can potentiate seizures in those that have used benzodiazepines chronically and those who have co-ingested a seizure-potentiating substance (eg, bupropion, tricyclic antidepressants, and lithium). The dosing scheme is to give 0.2 mg of flumazenil IV, then 0.3-mg IV if there is an insufficient response, then repeated doses of 0.5-mg IV up to a maximum of 3 mg.[74]

Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal. The major differences in management is the length of treatment.[73] The duration of withdrawal symptoms in patients physically dependent on benzodiazepines can be variable due to multiple factors including benzodiazepine dose, duration of use, duration of taper, and pharmacokinetic half-life.[75] Current recommendations suggest a gradual taper extending over 4 to 8 weeks and sometimes longer depending on the duration of use. It is recommended to reduce the daily dose approximately 10% to 25% every 2 weeks to decrease the risk of severe withdrawal reactions and seizures.[73] If a patient is taking multiple benzodiazepines, it is recommended to convert the patient to an equivalent single dose of diazepam, given its long half-life, and begin the taper as directed. There is limited evidence for converting a patient from a single short half-life benzodiazepine to a long half-life benzodiazepine so this practice is generally not recommended. With all benzodiazepines, protracted minor abstinence symptoms—such as anxiety, insomnia, irritability, sensitivity to light and sound, and muscle spasms—can remain for several weeks or longer in patients with a history of long-term exposure. This can occur even after the acute phase of benzodiazepine withdrawal is complete.[76] Additional information on benzodiazepine tapers can be found in Chapter 90.

INTRODUCTION: STIMULANTS, HALLUCINOGENS, AND CANNABINOIDS

⑫ Acute intoxication with stimulants, hallucinogens, cannabinoids, and other mind-altering substances continues to be a relevant issue around the world. Improved outcomes are achieved through prompt recognition of symptoms and supportive care. At the time of writing, no antidotes or targeted therapies are available for these agents. Active monitoring and management of vital organ function is often sufficient for a positive outcome. Chronic use disorder and withdrawal from these agents are complex disease states that can require inpatient monitoring. No medication-assisted therapy is available for the treatment of chronic use involving these agents. Data involving successful treatment of SUDs involving stimulants, cannabinoids, and cathinones is in its infancy. It likely requires outpatient follow-up and psychosocial intervention for long-term sustained recovery.

Stimulants

The physiologic and psychologic effects of amphetamines and other stimulants are qualitatively similar, as they diminish fatigue, increase alertness, and suppress appetite. In higher doses stimulants can lead to behavioral changes, perception disturbances, and frank psychosis. Pharmacologically, amphetamines increase the activity of catecholamine neurotransmitters (eg, norepinephrine and dopamine) by stimulating release, decreasing reuptake into the neuron through blocking of vesicular monoamine transporters (VMAT2), and by inhibiting the degradation via monoamine oxidase (MAO). Stimulants improve mood, self-confidence, energy levels, alertness, concentration, and physical performance. Negative consequences of stimulant use range from headache, palpitations, hypertension, tachycardia, dizziness, anxiety and insomnia to confusion, agitation, paranoia, convulsions, and delirium.

Methamphetamine

The pathophysiology of methamphetamine use disorder (MUD) results from dopamine, serotonin, norepinephrine, and epinephrine release from the synaptic vesicle into the cytosol.[77] Dopamine is also increased through several mechanisms such as the inhibition of monoamine oxidase and increase in tyrosine hydroxylase activity. However, excessive dopamine can also increase reactive oxygen species that lead to cell structure damage. With this damage, the brain's metabolic state is altered through acidification of the microenvironment, and dysregulation of cell signaling via reactive oxygen species. This mirrors degenerative central nervous system diseases. The resultant neuronal and microglia cellular dysregulation is associated with dysfunctional neural processing, altered reward motivation, and reduced prefrontal control. Through this, the imbalance in the orbitofrontal cortex of the brain leads to cognitive deterioration affecting valuation and decision making. This results in poor task performance, and inattention, which facilitates continued -seeking behavior. Mortality from MUD is commonly associated with cerebrovascular disease such as stroke, and cardiovascular disease such as cardiac collapse.[77] Because methamphetamine elevates mood, people who experiment with it tend to use it with increasing frequency and in increasing doses, despite their original intent.[78]

Methamphetamine is used orally, intranasally, rectally, intravenously, and by smoking. Immediately after inhalation or intravenous injection, the individual using methamphetamine experiences an intense sensation, called a "rush" or "flash," that lasts only a few minutes and is described as extremely pleasurable. The timing and intensity of the "rush" that accompanies methamphetamine use results from the release of high levels of dopamine in the brain, but this depends in part on the method of administration. Specifically, the effect is almost instantaneous when smoked or injected, whereas it takes approximately 5 minutes after snorting or 20 minutes after oral ingestion.[79] The duration of effect is about 12 hours per administration but can be altered by route of administration and individual characteristics.[78]

Methamphetamine-induced caries, or "meth mouth," is a characteristic pattern of dental decay commonly observed in patients that smoke methamphetamine. Prolonged use of methamphetamine can result in a tolerance for the medication and increased use at higher dosage levels, creating dependence. Such continual use of the medication with little or no sleep may lead to an extremely irritable and paranoid state. Discontinuing use of methamphetamine often results in a state of depression, as well as fatigue, anergia, and some types of cognitive impairment that can last from two days to several months.[79]

Healthcare providers working in the retail setting, such as pharmacists, should be wary of persons wishing to purchase large quantities of products containing nonprescription sympathomimetic products such as pseudoephedrine, as this is a key ingredient for methamphetamine production. As a precaution, federal legislation now limits the quantities that can be purchased, along with mandating pseudoephedrine-containing products be kept behind a counter, and suitable identification be shown before purchasing.

Cocaine

Cocaine is perhaps the most behaviorally reinforcing of all used substances. It acts as a local anesthetic through inhibition of voltage-gated sodium channels when topically applied. Cocaine also acts as a sympathetic nervous system stimulator through α- and β-adrenergic stimulation which can precipitate chest pain and myocardial infarction. In the CNS, the stimulant and euphoric effects occur through inhibition of dopamine and norepinephrine reuptake. The excess dopamine in the ventral tegmental area (VTA) leads to the psychostimulant properties, contributes to psychotic behavior, and portends a high rate of addiction.[80]

For many years, cocaine has been administered as the hydrochloride salt form, usually by insufflation, but also by injection. Conversion to the cocaine base, also known as "crack" or "rock," allows for smoke inhalation. This is generally a more inexpensive form and thus more widely available. The time to peak concentration is rapid for all routes but is fastest by intravenous injection (instantaneous), then smoking (6 minutes), and then finally nasal insufflation (45 minutes).[80] Smoking the drug leads to almost instant absorption and intense euphoria. The high from insufflating is more prolonged lasting 15 to 30 minutes, whereas the high from smoking rapidly dissipates lasting only 5 to 10 minutes. Cocaine is metabolized and eliminated rapidly, with a half-life of approximately 1 hour contributing to its very short duration of effect.[81] Therefore, the rapid onset and short duration combined provide a powerful incentive for repeated use of the drug. The primary cocaine metabolite (benzoylecgonine) may be detected up to five days in a urine sample with little cross-reactivity.[82] Increased use can reduce the period of stimulation and an appreciable tolerance to the high can develop. Many individuals that use cocaine report failing to achieve as much pleasure as they did from their first exposure with continued use which may lead to intense drug-use cycling, sometimes lasting days, characterized by rapidly repeating doses of cocaine until their money or supply is exhausted.

Other patterns of use such as consumption of alcohol along with cocaine are common and add to the toxicity. Such drug use would seem counterintuitive based on the counteracting effects of the two substances; however, in the presence of alcohol, cocaine is metabolized to cocaethylene, a longer-acting but potent psychoactive compound compared to the parent drug. The risk of death from cocaethylene is greater than from cocaine alone and this combination is one of the most common among individuals who come to hospital emergency departments with acute substance abuse problems.[81]

Clinical Presentation

CLINICAL PRESENTATION: Cocaine Intoxication and Withdrawal

General

- In overdoses, cocaine is a CNS and cardiac stimulant.
- Cocaine-related deaths are often a result of cardiac arrest or seizures followed by respiratory arrest.

Symptoms

- Symptoms of intoxication include motor agitation, elation, euphoria, hypervigilance, sweating, nausea, and vomiting.
- Symptoms of withdrawal include fatigue, sleep disturbances, nightmares, depression, and changes in appetite.

Signs

- Tachycardia, mydriasis, and elevated blood pressure may be observed with overdose.
- Cardiac abnormalities (eg, arrhythmias, infarction) and respiratory depression may be observed with overdose.
- Bradyarrhythmias and tremors may be observed in acute withdrawal.

Laboratory Tests

- Qualitative urine screening tests are available; however, they do not change clinical treatment significantly.

Other Diagnostic Tests

- Markers of organ dysfunction may be ordered as clinically indicated.

CLINICAL PRESENTATION: Amphetamine Intoxication and Withdrawal

General

- Amphetamine intoxication is an acute condition that may result in death. Pharmacotherapy may be indicated for symptomatic control of agitation, psychosis, and seizures.
- Patients may experience withdrawal symptoms for several days but are usually not in acute distress. Treatment of withdrawal is supportive in nature.

Symptoms

- Amphetamine intoxication may present as increased wakefulness, increased physical activity, decreased appetite, increased respiration, hyperthermia, and euphoria. Other CNS effects include irritability, insomnia, confusion, tremors, convulsions, anxiety, paranoia, chest pain, and aggressiveness. Hyperthermia and convulsions can result in death.
- Depression, altered mental status, substance craving, dyssomnia, and fatigue are all symptoms of withdrawal.

Signs

- Patients with amphetamine intoxication may present with tachycardia, hypertension, seizures, or stroke.

Laboratory Tests

- A qualitative urine screening can identify patients who have been exposed to amphetamines. However, false positives are common and the diagnostic benefit is limited.

Ecstasy

There are several dozen analogs of amphetamine and methamphetamine that are mildly hallucinogenic. Two methamphetamine analogs of most concern are 3,4-methylenedioxyamphetamine and especially 3,4-methylenedioxymethamphetamine (MDMA, Ecstasy or Molly). Ecstasy usually refers to a tablet or pill formulation whereas Molly is most often a powdered form that can be insufflated or smoked. Trends in MDMA use have been declining since its peak in 2001; however, the annual prevalence of use has held steady.[11]

Individuals that use MDMA report feelings of trust and empathy with others, decreased inhibition when socializing, and enhanced proprioception in addition to stimulating effects that MDMA shares with amphetamines. These effects are due to the preferential selectivity of MDMA for serotonergic over dopaminergic neurotransmission.[83] In addition to these positively reinforcing effects, MDMA use can result in negative effects such as panic, anxiety, depression, paranoid thinking, and psychosis. Physical symptoms include muscle tension, nausea, blurred vision, faintness, chills, and sweating, as well as vomiting, hyperthermia, dehydration, tremors, insomnia, and convulsions. Furthermore, MDMA also increases heart rate and blood pressure due to its structural similarities with amphetamines.[84]

In general, those that use MDMA perceive it to be a harmless drug, based in part on the fact that the risk of death is low compared with other drugs such as heroin and cocaine. However, mounting evidence points to MDMA's neurotoxic effects, involving a complex and incompletely understood mechanism. Mechanistically MDMA has been shown to destroy serotonergic neurons in animals, but further research is needed to understand the mechanism behind this loss of serotonin following MDMA exposure.[84] Recent publication of small studies exploring ecstasy being used therapeutically further complicates the assessment of MDMA's risks and benefits, as preliminary studies have been conducted in posttraumatic stress disorder (PTSD), anxiety disorders, and social anxiety in autism. It should be noted that most of these studies also include psychotherapy as part of the treatment regimen.[85,86]

Hallucinogens

The drugs commonly classified as hallucinogens are lysergic acid diethylamide (LSD), psilocybin, dimethyltryptamine (DMT), mescaline, phencyclidine (PCP), ketamine, and other related compounds. Approximately 1.4 million people aged 12 or older are estimated to be currently using hallucinogens, with variability seen in each age ranging from 0.6%, 1.7%, and 0.3% for adolescents, young adults, and adults, respectively.[11] These statistics may not include ketamine use as this was recently added to the NSDUH Survey. Pharmacologically, LSD and related drugs stimulate both presynaptic (5-HT_{1A} and 5-HT_{1B}) and postsynaptic (5-HT_2) serotonin receptors in the brain, which functionally can cause either agonist or antagonist effects on serotonin activity. Precisely how the hallucinogens exert their effects remains unclear. Overall, LSD is an extraordinarily potent compound, producing observable CNS effects at doses as low as 25 mcg. For an in-depth review of the history, current status, and future uses of LSD, the reader is directed to a review by Smith and colleagues.[87]

Cannabinoids

Cannabis use is common in the United States. Despite a multitude of states passing laws allowing medical use and recreational use, cannabis is still an illegal substance according to federal law. In addition, increased media attention surrounding potential medical uses has also contributed to the public's evolving beliefs surrounding its use. In 2019, an estimated 48 million (a steady increase since 2002) Americans aged 12 or older used cannabis which corresponds to 17.5% of this population.[11] This use is likely to increase for the foreseeable future making abuse and subsequent treatment an increasingly important topic for healthcare providers. Cannabinoids are the active compounds within most available products or preparations. One chemical component of cannabis is δ-9-tetrahydrocannabinol (THC) which interacts with the two cannabinoid receptors within the CNS to cause its euphoric and psychoactive effects. Cannabidiol (CBD) does not have psychoactive effects. Epidiolex™ is a CBD preparation, FDA approved to treat Lennox-Gastaut syndrome and Dravet syndrome, two disorders that leave the afflicted with refractory seizures.[88]

As a group, cannabinoids interact with two subsets of cannabinoid receptors in the body: cannabinoid receptor 1 (CB1) and cannabinoid receptor 2 (CB2). Anandamide and 2- arachidonoylglycerol are the endogenous complements to the CB receptors, although their effects have not been completely described. The CB1 receptors are found in presynaptic neurons of the prefrontal cortex and in the hippocampus, and the CB2 receptors are located in smaller numbers in the prefrontal cortex, hippocampus, and hypothalamus. However, they are thought to play a much larger role in systemic effects of cannabinoids due to their abundance in the immune, peripheral nervous, and gastrointestinal systems.[89] Since THC is a partial agonist at CB1 and CB2 receptors, it is thought to create its psychoactive effects through CB1 receptors. In contrast, CBD binds less tightly with CB receptors and may interact with other receptors within and outside of the CNS.[90] Although the knowledge base surrounding the pharmacology and pharmacodynamics of cannabinoids is rapidly expanding, the current knowledge regarding their therapeutic effects is relatively incomplete compared to other FDA-approved medications. While cannabis is most commonly smoked, it can be ingested orally with THC and CBD extracts now being incorporated into many other usable forms including edible candies/snacks and vaporizable liquids that can be more palatable for new, young, or those not experienced in using cannabis. Cannadinoid pharmacokinetic properties are not well characterized, but they do show highly variable effects that are greatly affected by route of use. After inhalation of smoke or vapors, peak blood concentrations occurs in about 10 minutes and although bioavailability is higher through inhalation relative to oral ingestion, many factors can affect this. Both THC and CBD are poorly bioavailable due to extensive first-pass metabolism by the liver; therefore, peak concentrations occur at about 2 hours when taken via the oral route. The terminal half-life of THC and CBD after a single use is about 24 hours; however, in those that use chronically, the terminal half-life is highly altered due to accumulation and subsequent redistribution from fatty tissues after chronic use.[90]

Cannabis use disorder (CUD) is loss of control over use, repeated failures to quit, and continuous usage despite negative consequences. The pathophysiology of CUD lies in chronic neuroadaptation over time. The primary euphoric psychoactive component of cannabis THC targets the body's natural endogenous endocannabinoid system leading to downregulation in those that use chronically. This downregulation results in alterations to the processes that regulate cognition, emotional processing, stress sensitivity, and reward goal directed behavior occurs. Additionally, THC-induced alterations modify synaptic plasticity, specifically leading to a reduction in synapses of the hippocampal neurons.[91]

⑬ According to the *DSM-5*, CUD leads to significant social impairment and or psychological distress in spite of negative personal consequences.[92] It is often associated with multiple failed attempts at halting cannabis use, with the rate of occurrence in North America being estimated to be as high as 749 in 100,000.[93] Although CUD has quite a high incidence, its detection and treatment are limited in part by beliefs that cannabis is safe and natural.[91] Abrupt discontinuation of cannabis use can elicit a withdrawal syndrome including anxiety, dysphoria, sleep changes, irritability, and anorexia. Although not life threatening, these withdrawal symptoms can make permanent discontinuation difficult. Treatment of CUD most often centers around psychosocial interventions such as cognitive behavioral therapy (CBT), motivational enhancement therapy (MET), or a combination there of. Both CBT and MET have been shown to decrease the number of days of cannabis use, and improve the severity of CUD. Additionally, CBT has been shown to increase abstinence rates where MET has yet to show this effect in clinical studies. Regardless, the combination of CBT and MET is synergistic.[91] Attempts at using pharmacotherapeutic agents to alleviate CUD have been mostly unsuccessful with escitalopram, fluoxetine, bupropion, nefazodone, venlafaxine, valproate, baclofen, modafinil, atomoxetine, buspirone, and naltrexone all proving ineffective. However, several therapeutic candidates have met with some success. Cannabinoid receptor agonists including dronabinol, nabilone (a synthetic THC analogue), and nabiximols (Satívex, a combination THC/CBD product) have had varying degrees of success in improving withdrawal symptoms in CUD. One small study found gabapentin was effective in decreasing cannabis use in addition to abating withdrawal symptoms. N-Acetylcysteine, a cysteine precursor thought to affect glutamate transmission, decreased rates of cannabis use in adolescents. However, follow-up studies in adults did not confirm these results. Regardless these studies should be interpreted and extrapolated cautiously due to the low number of patients involved.[91]

Synthetic Cannabinoids

A growing collection of synthetically derived cannabinoids are being misused for their psychoactive effects. Following identification of THC in 1964, and the endogenous cannabinoid receptors in the 1980s, there was a pharmaceutical effort to synthesize cannabinoid receptor agonists for potential therapeutic indications like nausea and pain. However, the vast majority of these efforts never reached commercial fruition, and they have begun showing up in the illicit market. To increase their attractiveness, they are often brightly packaged and given colorful names such as “K2,” “Spice,” “Aroma,” “Mr. Smiley,” “Zohai,” “Eclipse,” “Black Mamba,” “Red X Dawn,” “Blaze,” and “Dream.” Due to unclear laws regarding their legality, these products had been readily available at gas stations and convenience stores. However, since being listed as a schedule I controlled substance, the overt availability has decreased but they are still readily available.[94] Some synthetic cannabinoids produce a combination of intended effects, as well as unintended adverse effects, that resemble intoxication from THC. However, synthetic cannabinoids appear to be more potent than natural cannabinoids, and may interact with CB receptors for longer than THC. Symptoms of synthetic cannabinoid toxicity are similar to the euphoric and psychoactive effects of THC. The adverse effects of synthetic cannabinoids include severe agitation, anxiety, nausea, vomiting, tachycardia, elevated blood pressure, tremors, seizures, hallucinations, paranoid behavior, and nonresponsiveness. These effects are likely due to complex CB1 receptor interactions, direct and indirect, with dopaminergic, serotonergic, and glutaminergic pathways within the parts of the brain linked to psychosis.[95] However, it must not be forgotten that most reported adverse experiences with synthetic cannabinoids are troubled by incomplete knowledge of the specific cannabinoid product used, as well as adulteration with other substances.

Cannabis Hyperemesis Syndrome

⑭ Cannabinoid hyperemesis syndrome (CHS) is a syndrome of cyclical vomiting in individuals with habitual use of cannabis that abates after discontinuation of use. Although first officially recognized in 2004, the syndrome has likely existed much longer. The pathophysiology underlying CHS is not completely elucidated and several hypotheses are being explored. Since cannabinoids are used therapeutically to treat chemotherapy associated nausea and vomiting, current hypotheses indicate that pathway signaling may be altered in a way that leads to excessive nausea and vomiting. Cannabinoids are also known to alter gastrointestinal hormones, potentially leading to aberrant GI function such as emesis. Other potential explanations include non-THC metabolite interactions, genetic variations in metabolism of cannabinoids, and vasodilation of splanchnic vascular beds.[96] Overall, CHS can be difficult to diagnose as nausea and vomiting are symptoms of many issues, and patients may not be forthcoming with their cannabis use due to its questionable legality. One interesting symptom, that often sets CHS apart from other causes of severe vomiting, is that CHS sufferers often report relief from hot baths or showers.

A systematic review found that CHS is diagnosed in males with greater frequency. The median age when cannabis use started was 16 years and the median age when symptoms developed was 24 years. The fact there is a long pattern of use before CHS develops which makes it harder to diagnose as both the person using as well as the clinician are likely to consider more recent changes or developments over chronic use. In the same review, all people diagnosed with CHS self-identified as using it at least weekly and a large majority (~75%) used daily. There are no consensus diagnostic criteria now.[96] Treatment of CHS is also far from standardized due to an incomplete delineation of causative mechanism. Abstinence from cannabis is the most effective treatment option, but takes several days to weeks for the cyclic vomiting to abate. While the use of hot bathing is effective for some people, its benefit is short-lived and it is not a sustainable treatment modality.[97] If intravenous fluids and traditional antiemetics are unsuccessful at improving CHS symptoms, other treatment options that are less established have been reported. Dopamine antagonists like haloperidol have been used successfully in small case reports.[98] A growing number of case reports have shown some benefit with topical capsaicin application which is thought to interact with the transient receptor potential cation channel subfamily V member 1 or vanilloid receptor 1 (TRVP1 or VR1) to improve nausea and vomiting, although the mechanism isn't clearly understood.[96,97,99,100] The incidence of CHS is likely to increase as the availability of cannabis use increases and the potency of THC-containing products increases.

EVALUATION OF THERAPEUTIC OUTCOMES

There are a range of situations and substances where patients can present in regards to substance use. When considering overall therapeutic outcomes, each treatment must be evaluated to determine its efficacy and safety as there are a variety of factors that must be considered based on the current stage of therapy and the patient's specific treatment goals. Each of the medications used in the acute or the chronic setting have unique qualities that must be evaluated for each individual patient. Consistent monitoring for efficacy and appropriateness through treatment is critical. Monitoring for withdrawal reactions utilizing proper assessment scales (ie, COWS) can aid in evaluating the patient appropriately. When developing the treatment plans, the unique adverse effect profiles and medication and drug-interaction concerns for the selected treatment regimen must be considered. Data from urine drug screens and profiles from the Prescription Drug Monitoring Program (PDMP) can also help provide critical information on the full clinical picture for each patient. Patient education must occur throughout treatment to ensure proper medication administration and safety as therapy continues. SUD is a chronic disorder that will need not only pharmacological treatment but also ongoing psychosocial and educational support. It is important for healthcare providers working in this setting, to partner closely with the patient to continue setting appropriate goals in order to achieve favorable treatment outcomes.

CONCLUSION

OUD along with other SUDs continue to be escalating health problem in the United States. The true scope of the problem has only recently been explored. Management of OUD and SUD, whether through pharmacotherapy or behavioral therapy, is a rapidly progressing field. Healthcare providers can help in all aspects of tackling this problem, from identifying those with SUD, directing pharmacotherapy, assisting with treatment, and patient education using a patient-centered model.

SELF-ASSESSMENT QUESTIONS

1. In which year did opioid prescriptions peak in the United States?
   - A. 2010
   - B. 2011
   - C. 2012
   - D. 2016
2. Which of the following statements is FALSE regarding fentanyl products?
   - A. Most opioid overdose deaths attributed to fentanyl have been linked to prescription fentanyl products.
   - B. llicit manufactured fentanyl (IMF) is often mixed with heroin or cocaine which is leading to increases in overdose deaths across America as per data released in 2018.
   - C. IMF has been identified in counterfeit opioids and benzodiazepines pills and capsules.
   - D. Carfentanil is 10,000 times more potent than morphine and poses a severe threat to first responders due to the potency of the opioid.
3. Which medication treatment for OUD requires the patient to be abstinent from short- acting opioids for 7 to 10 days or long-acting opioids for 10 to 14 days?
   - A. Methadone
   - B. Buphrenorphine
   - C. Extended-release Naloxone
   - D. Ketamine
4. What is a key counseling point that should be covered regarding buprenorphine therapy?
   - A. All symptoms of craving will be immediately eliminated after starting this medication.
   - B. There are very few side effects to this medication so no need for follow-up.
   - C. The goal of the first week is to improve withdrawal symptoms without over-sedation.
   - D. There are no drug-drug interactions with this medication so no need to worry about this.
5. Which of the following statements is TRUE regarding naloxone?
   - A. Naloxone can be very dangerous if administered to a patient who is not currently taking an opioid.
   - B. The Narcan Nasal Spray and the Evzio auto-injector are approved by the FDA for community distribution.
   - C. Naloxone is effective at reversing benzodiazepine overdoses and opioids.
   - D. If a patient is overdosing on opioids and is also suffering from alcohol poisoning, then there is no reason to use the naloxone since it is ineffective.

6. Which of the following is FALSE regarding prescribing restrictions for buprenorphine?

   A. Based on recent legislation, certified nurse midwives can prescribe buprenorphine if allowed by state prescribing laws.

   B. Practitioners who are in compliance with DATA 2000 and have been confirmed to have the "X" DEA number can prescribe buprenorphine for up to 300 patients.

   C. Buprenorphine is a schedule III controlled substance with very specific prescribing restrictions.

   D. Physician assistants and nurse practitioners are authorized to prescribe buprenorphine as long as it is approved by state licensing.

7. Which of the following routes of cocaine use has the fastest time of onset and highest peak blood concentration?

   A. Oral ingestion of crack cocaine

   B. Nasal insufflation of cocaine

   C. Smoking crack cocaine

   D. Intravenous injection of cocaine

8. Which of the following neurotransmitter systems plays a major role in the toxicity of stimulants, such as cocaine, based on current understanding?

   A. Histamine

   B. Dopamine

   C. Norepinephrine

   D. GABA

9. Which of the following is the cannabinoid associated with the psychoactive effects of cannabis?

   A. Anandamide

   B. 2-arachidonoylglycerol

   C. Cannabidiol

   D. Tetrahydrocannabinol

10. Symptoms of cannabis hyperemesis syndrome (CHS) are potentially relieved by which of the following treatments.

   A. Warm showers

   B. Smoking cannabis

   C. Gabapentin

   D. Cold showers

11. What is the incidence of opioids and benzodiazepines being co-prescribed?

   A. 20%

   B. 40%

   C. 60%

D. 80%

12. Which over-the-counter (OTC) medication is regulated in an effort to prevent the production of methamphetamine?

    A. Certrizine

    B. Pseudoephedrine

    C. Diphenhydramine

    D. Epinephrine

13. Use of which of the following substances can lead to adverse effects similar to amphetamine toxicity based on similar structural elements?

    A. Cannabis

    B. Ecstasy

    C. Carfentanyl

    D. Heroin

14. Current recommendations for a pregnant woman with an OUD requesting treatment includes:

    A. Naloxone.

    B. Methadone.

    C. Extended-release injectable naltrexone.

    D. No medications are recommended.

15. What is the main difference between the treatment of benzodazepine withdrawal and alcohol withdrawal?

    A. The half-life of the benzodiazepine used.

    B. The length of treatment.

    C. Alcohol withdrawal protocols only start if withdrawal symptoms are seen.

    D. Treatment for withdrawal from a benzodiazpine is not medically managed.

SELF- ASSESSMENT QUESTION-ANSWERS

1. **C.** In 2012, opioid prescriptions in the United States peaked at 255 million annual prescriptions.

2. **A.** Most fentanyl linked overdoses have been associated with IMF. For more information see the "Fentanyl" section.

3. **C.** Patients starting extended-release naloxone must have an adequate time period of opioid abstinence before starting this medication as opioids in the system can precipitate withdrawal necessitating hospitalization. For further information, see the chapter text and Table 85-1.

4. **C.** The first week is focused on identifying a dose that will help withdrawal symptoms without over-sedating the patient. Moving forward, it will be important to work on stabilizing the patient and working to encourage behavioral therapy to go with the pharmacotherapy treatment.

5. **B.** Narcan Nasal Spray and Evzio auto injectors are both approved by the FDA for community distribution. For further information see the text and Table 85-2.

6. **C.** This bill codified that waivered physicians can prescribe MAT for 275 patients. For more information see the "Buprenorphine" section.

7. **D.** Since IV administration of cocaine bypasses the first pass effect, this results in the fastest time of onset and highest peak blood concentration. For more information see the "Cocaine" section.

8. **C.** While dopamine plays a key role in the reward and addiction pathways, norepinephrine is responsible for the toxic sympathomimetic effects experienced by users of cocaine. For more information see the "Cocaine" section.

9. **D.** Tetrahydrocannabinol is the primary cannabinol associated with the psychoactive effects of cannabis.

10. **A.** Warm showers can help alleviate the vomiting and can be a diagnostic clue if reported by the patient.

11. **D.** A cohort study that included over 2 million opioid prescriptions in one year demonstrated 80% of these were co-prescribed with a benzodiazepine and the rates of overdose deaths in this group were 10 times higher than opioid analgesics alone. See "Epidemiology" in "Benzodiazepines and Other Sedative-hypnotics" section.

12. **B.** Small laboratories use OTC products containing pseudoephedrine as starting product for the clandestine manufacture of methamphetamine. See the "Stimulant" section for more information

13. **B.** Ecstasy or 3,4-methylenedioxymethamphetamine (MDMA) is a structural analog of methamphetamine and can lead to hypertension, tachycardia, agitation, and psychosis. For more information, see the "Stimulants" section.

14. **B.** Current recommendations for a pregnant woman with an OUD requesting treatment includes methadone or buprenorphine, and behavioral interventions. Now, the safety of extended-release injectable naltrexone is still under study. See "Opioid Use Disorder" in "Pregnancy" section.

15. **B.** Treatment of benzodiazepine withdrawal is very similar to the treatment of alcohol withdrawal. The major differences in management is the length of treatment. See the "Pharmacologic Therapy for Benzodiazepine Intoxication and Withdrawal" section.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 86: Substance Use Disorders II: Alcohol, Nicotine, and Caffeine

Lori Dupree; Robin Moorman Li

KEY CONCEPTS

KEY CONCEPTS

① Globally, more than 3 million people, predominantly males, died in 2016 from alcohol consumption, which represents 1 in 20 deaths.

② Studies have identified genotypic and functional phenotypic variants that either serve to protect or predispose individuals toward developing an alcohol use disorder.

③ The metabolism of alcohol follows zero-order kinetics, except at very high and very low blood concentrations. This has important implications for the time course for the effects of alcohol.

④ Disulfiram, naltrexone, extended-release naltrexone, and acamprosate are FDA-approved for the treatment of alcohol use disorder. Their clinical utility to improve sustained abstinence and reduce heavy drinking remains controversial.

⑤ Tobacco is the most preventable cause of death in the United States.

⑥ Clinicians should ask all individuals about tobacco use, advise on how to stop using tobacco products, and provide pharmacotherapy and behavioral treatment options to aid in smoking cessation.

⑦ All forms of nicotine replacement therapy are effective in reducing the amount smoked and achieving abstinence.

⑧ Varenicline has similar efficacy to the nicotine patch and may be more efficacious than all other single nicotine replacement therapies (NRTs). It is approved for up to 6 months of maintenance therapy by the Food and Drug Administration (FDA).

⑨ As many as one in five adults consume doses of caffeine generally considered large enough to cause clinical symptoms.

⑩ Energy drinks continue to be popular, particularly among adolescents and emerging adults. Concerns have been raised regarding the safety of these products.

BEYOND THE BOOK

BEYOND THE BOOK

Alcohol Use Disorder

Watch this five-minute video titled "Brief intervention: Steve," which provides an example of an outpatient clinician making an intervention on an individual with unhealthy alcohol use. This video enhances understanding of how the AUDIT tool can help collect information during an interview and how motivational interviewing can effectively help individuals realize their problem and develop a plan of action.

https://tinyurl.com/y5xvt3u3

1. The patient in the video scored in Zone 2 of the AUDIT questionnaire. Describe how you would interpret those results.
2. Motivational interviewing is a counseling approach where clinicians use a patient-centered stance in combination with techniques to help patients explore and resolve their own mixed feelings about changing unhealthy behaviors.

   The principles of motivational interviewing include:

   - Expressing empathy—building rapport and engaging the patient by seeking to understand his/her perspective
   - Developing discrepancy—determining the patient's perception of how well current behaviors match desired behaviors
   - Rolling with resistance—letting the patient make the arguments for a change instead of the clinician arguing for change
   - Supporting self-efficacy—using reflective statements to restate the patient's belief which he/she verbalized to be able to change a specific behavior

In the video, which principle(s) of motivational interviewing did the clinician utilize when interviewing the patient?

Smoking Cessation

1. Review the brief case provided.
2. Watch the 3-minute video titled, "The 5As in Practice: Role Play of a Brief Intervention," which provides an example of the 5As in smoking cessation used in the clinic setting.

https://tinyurl.com/y437notb

3. List treatment recommendations that could be considered for this patient's case. Further instructions provided with the table.

Case:

A 43-year-old patient presented to primary care 2 weeks ago for treatment for a chronic productive cough. During this visit, a smoking cessation discussion was captured (see video above), and it was determined they would begin the nicotine patches in 1 week. They are now returning 2 weeks later reporting an adverse reaction to the patch adhesive. They have called the quitline once but would like some other recommendations from you in regard to strategies for smoking cessation as well. What would you recommend?

PMH:

Asthma

Allergies:

PCN

Adhesive (just added today to medical record from experience from nicotine patches)

Completing the table below will help complete the Implement section of the PPCP

Goals of therapy		
	Recommendation #1	Recommendation #2
Medication(s)		
Name, dose, route, etc.		
Rationale for recommended action		
Pros		
Cons		
Possible adverse effects		
Other concerns		
Behavior intervention recommendations		

INTRODUCTION—ALCOHOL

① Alcohol, nicotine, and caffeine are considered to be socially acceptable substances, yet they impose enormous social and economic costs on our society. The World Health Organization (WHO) estimates that in 2016, there were more than 3 million people worldwide who died from alcohol consumption with the majority being males. Long-term unhealthy alcohol use often leads to chronic disease, and a causal relationship has been established between unhealthy use and at least 200 types of chronic disease or injury worldwide (eg, cancers, liver disease, cardiovascular disease, seizures, homicide, HIV/AIDS, and motor vehicle accidents).[1] Nationally, alcohol contributes to approximately 18.5% of emergency department visits, and more than 95,000 people die annually from alcohol-related causes. This makes alcohol one of the leading causes of preventable death in the United States.[2]

EPIDEMIOLOGY

According to the National Survey on Drug Use and Health (NSDUH), 139.7 million Americans over age 12 reported current alcohol use, with 11.5% reporting heavy alcohol use. Additionally, 47.1% report binge alcohol use, defined as consuming five drinks or more on the same occasion on at least one day in the past 30 days for males and four drinks or more on the same occasion on at least one day in the past 30 days for females.[3] Furthermore, 1.2% reported heavy alcohol use, defined as binge drinking on 5 days or more in the past 30 days. It is estimated that 1 in 10 adolescents between the ages of 12 and 17 years are current alcohol users, which equates to 2.3 million young adults in one month.[3] Although, over the last 5 years, there has been an overall decline in alcohol use in this age group, within this specific age range, there are over 208,000 adolescents who are currently heavy alcohol users. In contrast, the estimates of heavy alcohol users in 2019 decreased to 2.8 million for individuals between the ages of 18 and 25, and 13 million for those 26 years and older.[3]

② The disease concept of addiction, using alcoholism as a model, states that individuals who suffer from the disease do not choose to contract the disease any more than someone who suffers from heart disease or diabetes mellitus chooses to contract that illness. Alcohol use disorder (AUD) is a chronic disease characterized by problematic and uncontrolled drinking and is diagnosed based on DSM-5 criteria, which requires 2 of the 11 criteria to be met during a 12-month period. The DSM-5 criteria ask 11 questions about the amount of alcohol use, the effects of alcohol use both personally and professionally, and any presence of withdrawal symptoms in the past year. Severity is determined based on the number of criteria met and subsequently classified as mild (2-3 symptoms), moderate (4-5 symptoms), or severe (6 or more symptoms).[4,5] See Chapter e84, "Introduction to Substance Use Disorders," for more information.

It has long been recognized that unhealthy alcohol use is heritable, as 50% of first-degree relatives of people with AUD become alcohol-dependent themselves.[6–8] Similarly, twin and adoption studies have had comparable results.[8] Additional research continues to identify common and rare genetic variations leading to not only variations in responses to alcohol but also the response to the pharmacological treatment of AUDs. Prospective data are lacking to determine the effects of genetic polymorphisms on individual responses of medications to treat AUD.[6,7] Large-scale pharmacoepidemiologic studies have further elucidated the environmental risk factors associated with either protective effects or predisposition toward unhealthy alcohol use (Table 86-1).[9]

TABLE 86-1

Genotypic, Phenotypic, and Environmental Factors That Increase Alcohol-Use Disorder Risk

Susceptibility Genes	Phenotype	Environment
Regions on chromosomes 1 and 4 that code for the following receptors: • $GABA_A$ • Serotonin 1B • DRD4 • Neuropeptide Y	Personality traits that include: • Novelty seeking • Impulsivity • Aggression • Depression • Early Exposure • Maximum number of alcoholic drinks consumed per day	• Religious background • Urban residence (vs rural) • History of sexual abuse • Being single • Having deceased parents
Gene that codes for: • ADH1B • ALDH2 • 5HTTLPR		

ADH1B, alcohol dehydrogenase 1B; ALDH2, aldehyde dehydrogenase 2; DRD4, type 4 dopamine receptor gene; GABA, γ-aminobutyric acid; 5HTTLPR, 5 hydroxytryptamine transporter.

Data from References 6,7,9.

ETIOLOGY

Alcohol is a central nervous system (CNS) depressant that acts in a dose-dependent fashion, producing sedation that progresses to sleep, unconsciousness, coma, and finally fatal respiratory depression potentially leading to cardiovascular collapse. Alcohol affects endogenous opiates and several neurotransmitter systems in the brain, including γ-aminobutyric acid (GABA), glutamate, serotonin, and dopamine. Alcohol is available in a variety of concentrations in various alcoholic beverages. There is approximately 14 g of alcohol in a 12-oz (355 mL) can of beer (approximately 5%), in 5 oz (148 mL) of nonfortified wine (approximately 12%), or in one shot (1.5 oz [44 mL]) of 80-proof whiskey (40%).[8,11] Full consumption of this amount will cause an increase in blood alcohol level of approximately 20 to 25 mg/dL (4.3 to 5.4 mmol/L) in a healthy 70-kg (154 lb) male, although this varies with the time frame of alcohol consumption, the type of alcoholic beverage, whether food is consumed co-currently, and many other patient-specific variables. The lethal dose of alcohol in humans is variable, but deaths generally occur when blood alcohol levels are greater than 400 to 500 mg/dL (87-109 mmol/L).[12]

PATHOPHYSIOLOGY

Approximately 20% of alcohol is absorbed through the stomach, with the remaining through the small intestine. Absorption begins in the stomach within 5 to 10 minutes of oral ingestion, with the onset of clinical effects following fairly rapidly. Peak serum concentrations of alcohol are usually achieved 30 to 90 minutes after finishing the last drink, although this depends on the type of alcoholic beverage, type and timing of food consumption, and other factors.[11,13]

More than 90% of alcohol in the plasma is metabolized in the liver by three enzyme systems that operate within the hepatocyte. The first system is metabolism to acetaldehyde by alcohol dehydrogenase (ADH) in the liver cell. In turn, acetaldehyde is metabolized to carbon dioxide and water by the enzyme aldehyde dehydrogenase (ALDH). A second pathway for oxidation of alcohol uses catalase, an enzyme located in the peroxisomes and microsomes. The third enzyme system, the microsomal alcohol oxidase system, has a role in the oxidation of alcohol to acetaldehyde. These last two mechanisms are of lesser importance than the alcohol dehydrogenase–aldehyde dehydrogenase system.[13,14] Beyond these, the remainder of alcohol is excreted by the lungs, and in urine and sweat.

③ The elimination of alcohol generally follows zero-order pharmacokinetics, where the concentration of alcohol in the blood decreases at a constant amount per unit of time. This can, in fact, be an oversimplification because at very high or very low concentrations elimination can follow first-order pharmacokinetics, where a constant percentage of alcohol is eliminated per unit of time. Blood alcohol concentration (BAC) measures the amount of alcohol present in the blood, and as BAC rises, the alcohol can result in different levels of impairment (Table 86-2) and the relationship between alcohol consumption and BAC is variable. On average, the BAC is lowered from 15 to 22.2 mg/dL (3.3-4.8 mmol/L) per hour in the nontolerant individual, assuming that the individual is in the post-absorptive state. In healthy males and females, alcohol has a volume of distribution of 0.7 and 0.6 L/kg, which corresponds closely with total body water.[15]

TABLE 86-2

Specific Effects of Alcohol Related to Blood Alcohol Concentration

BAC (%)[*] (mmol/L)	Type of Impairment	Effect(s)
0.0-0.05 (0-11)	Mild	Mild speech/memory/attention/coordination/balance impairment, relaxation, sleepiness
0.06-0.15 (12-34)	Increased	Impaired speech/memory/attention/coordination/balance, risk of aggression, significantly impaired driving skills, increased risk of injury to self and others, moderate memory impairment
0.16-0.30 (35-65)	Severe	Impaired speech/memory/attention/coordination/reaction time, balance significantly impaired, driving skills dangerously impaired, judgment and decision making dangerously impaired, blackouts, vomiting, and signs of alcohol poisoning common, loss of consciousness
0.31-0.45 (66-98)	Life-threatening	Loss of consciousness, danger of life-threatening alcohol poisoning, significant risk of death

[*] Grams of ethyl alcohol per 100 mL of whole blood.

BAC, blood alcohol concentration.

Data from Reference 22.

CLINICAL PRESENTATION

Screening for Alcohol Use Disorder

The CAGE questionnaire is a mnemonic for four questions: (a) Have you ever felt the need to cut down on your drinking? (b) Have people *a*nnoyed you by criticizing your drinking? (c) Have you ever felt bad or *g*uilty about your drinking? (d) Have you ever had a drink the first thing in the morning to steady your nerves or get rid of a hangover ("eye opener")? This commonly used tool can be used for detecting individuals more likely to be misusing alcohol and therefore at greater risk for alcohol withdrawal. Each question is scored as 0 for a "no" answer and 1 for a "yes" answer. A positive response, a total of 2 or more to these four questions, suggests an increased likelihood of unhealthy alcohol use with an average sensitivity of 0.71 (71%) and an average specificity of 0.90 (90%).[17]

The Alcohol Use Disorders Identification Test (AUDIT) is a validated 10-question screening tool originally developed to screen for alcohol use disorder and the amount and frequency of alcohol consumption in adults in the primary care setting. This screening tool can be completed by the patient or can be completed via an interview with a healthcare provider. Each question is scored from 0 to 4. Out of a possible score of 40, scores greater than 8 indicate harmful or hazardous drinking. Scores higher than 13 for females and 15 for males necessitate further evaluation for alcohol use disorder.[18] The AUDIT tool, as well as a short version of AUDIT (AUDIT-C), has been used within a broad range of patient populations and is an appropriate first step in identifying those struggling with unhealthy alcohol use. However, a new adaptation of the AUDIT, the USAUDIT, was adapted to US standard drink size and hazardous drinking guidelines and has been developed to more accurately detect drinking in excess of recommended levels.[18]

Acute Effects of Alcohol

At lower serum concentrations, euphoria and disinhibition may be noted. Additionally, slurred speech, altered perception of the environment, impaired judgment, ataxia, incoordination, nystagmus, and hyperreflexia may occur. As plasma levels increase, combative and destructive behavior may occur. With higher levels still, somnolence and respiratory depression may ensue.[16] The typical effects of various BACs are shown in Table 86-3, although effects vary from individual to individual.

Alcohol Poisoning

Acute alcohol poisoning, also commonly referred to as alcohol overdose, usually occurs with the rapid consumption of large quantities of alcoholic beverages. With sustained drinking of moderate alcohol amounts, the user passes out before a toxic dose can be ingested, and/or the person vomits to rid the stomach of its toxic reservoir. With rapid drinking, the person may fall asleep or pass out without vomiting, allowing continued alcohol absorption from the gastrointestinal (GI) tract until fatal BACs are achieved.[16]

Laboratory Studies

In the emergency room, a BAC should be ordered in any patient in whom alcohol ingestion is suspected, regardless of the presenting complaint. For clinical purposes, most laboratories report BAC in units of mg/dL or mmol/L. In legal cases, results are reported in percentage (grams of ethyl alcohol per 100 mL of whole blood). Along with a BAC, a complete blood count should be ordered to assess for anemia and a complete metabolic panel plus serum magnesium should be ordered to assess electrolytes, glucose, and renal and liver function. If the diagnosis is unclear, if the intoxication seems atypical, or when there is suspicion of multiple substance ingestions, a complete toxicologic screen may be useful to rule out other substances.[19]

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Alcohol Withdrawal

General

- Acute alcohol detoxification and withdrawal after chronic unhealthy alcohol use is a serious condition that can require hospitalization and adjunctive pharmacotherapy.
- At a very high BAC, death is possible.

Symptoms

- The intoxicated individual can present with slurred speech and ataxia. The patient can be sedated or unconscious.
- As BACs decrease rapidly, nausea, vomiting, tremors, and hallucinations can ensue. Delirium tremens (DT) and seizures are the most severe symptoms.
- An evaluation should be completed using the Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar), a 10-item scale to document and score the patient’s baseline symptoms (nausea and vomiting, tremors, paroxysmal sweats, anxiety, tactile/auditory/visual disturbances, headache, agitation, orientation and clouding of sensorium).

Signs

- The intoxicated individual can present with nystagmus.
- In withdrawal, the individual can present with tachycardia, diaphoresis, hypertension, and/or hyperthermia.

Laboratory Tests

- In the emergency department, a BAC should be ordered when alcohol ingestion is suspected. A whole blood alcohol level of 150 mg/dL (33 mmol/L) reported in the hospital corresponds to 0.15% BAC obtained by law enforcement.
- Order a complete blood count to assess for anemia, a complete metabolic panel to assess electrolytes, glucose, renal, and liver function, and serum magnesium.
- A complete toxicologic screen to rule out the presence of other substances can be useful.

Other Diagnostic Tests

- Differentiate acute alcohol intoxication from other medical illnesses (eg, head trauma).
- Order computed tomography (CT) on any patient with focal neurologic findings, failure to improve, new-onset seizures, or mental status out of proportion to the degree of intoxication.

TREATMENT

Desired Outcomes

While alcohol withdrawal most likely occurs in the face of alcohol use disorder, it is necessary to treat acute withdrawal symptoms (or prevent them from occurring) before other alcohol use disorder treatments are started. The goals for alcohol-dependent persons trying to decrease or discontinue alcohol intake include (a) the prevention and treatment of withdrawal symptoms (including withdrawal seizures and DT) and medical or psychiatric complications, (b) long-term abstinence after detoxification, and (c) entry into ongoing medical and unhealthy alcohol use treatment.[20]

Nonpharmacologic Therapy

Due to the severity of signs and symptoms and associated morbidity and mortality with alcohol withdrawal, nonpharmacologic therapy is not recommended. Patients with alcohol withdrawal require a coordinated approach in a monitored setting with the use of inpatient, outpatient, and rehabilitation services.[19]

Pharmacologic Therapy

A baseline assessment using a validated tool, such as the Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar), should be completed.[21] Symptom-triggered treatment with a benzodiazepine is the current standard of care in alcohol detoxification to assess severity and avoid progression to more severe withdrawal stages. All benzodiazepines appear to be similarly efficacious in reducing the signs and symptoms of withdrawal. However, there are pharmacokinetic differences (ie, onset of action, duration, metabolism) between benzodiazepines, in addition to route of administration and cost, that guide pharmacotherapy decisions.[19,22,23]

Benzodiazepines are first-line treatment and the standard of care, given their documented efficacy in reducing the signs and symptoms of withdrawal.[23] Other agents with activity on the GABA system have been evaluated in the treatment of alcohol withdrawal. A Cochrane review[24] of the efficacy and safety of pharmacological options in treating alcohol withdrawal syndrome included a total of 7,333 patients. The medications evaluated included benzodiazepines, baclofen, antiseizure medications (ie, phenobarbital, valproic acid, carbamazepine, gabapentin, topiramate), and psychotropic analgesic nitrous oxide (PAN), along with gamma-hydroxybutyrate. Efficacy was determined based on the impact on alcohol withdrawal seizures. Benzodiazepines were more efficacious when compared to both placebo (RR 0.16; 95% CI 0.04-0.69) and antipsychotics (RR 0.24; 95% CI 0.07–0.88). Within the benzodiazepine class comparison, there was a trend toward better efficacy with chlordiazepoxide; however, no benzodiazepine was shown to be superior.[24] Phenobarbital, with a rapid onset of action and a long half-life, is the most commonly used alternative to benzodiazepines in alcohol withdrawal, demonstrating efficacy and safety with monitoring when used alone or in combination with benzodiazepines.[19,23]

Treatment Regimens

Front-Loading Therapy

One initial approach to managing alcohol withdrawal includes using an initial high dose of a long-acting benzodiazepine, such as diazepam 10 to 20 mg or chlordiazepoxide 100 mg, and administered in repeated doses every 1 to 2 hours until the patient is sedated. Adequate sedation is usually obtained after three doses. Front-loading therapy is recommended when the CIWA-Ar score is 19 or above. Patients must be closely monitored under clinical supervision for benzodiazepine toxicity, such as excessive sedation, respiratory depression, and delirium. This approach should be used with extreme caution in older patients or in those with liver disease since the elimination rate will be extended, leading to an increased risk of toxicity.[22,23]

Symptom-Triggered Therapy

With symptom-triggered therapy, medication is given only when the patient has symptoms and the CIWA-Ar score is 8 or above. Various benzodiazepines have been used in this therapy, including diazepam, chlordiazepoxide, oxazepam, and lorazepam. Agent choice depends on the patient's age, liver function, available dosage forms, the hospital's formulary, and cost. The patient is then reassessed hourly utilizing the CIWA-Ar. If the score remains above 8, they continue to receive a dose of the selected benzodiazepine. If the score is lower than 8 and the patient appears stable, the time frame for assessment and treatment can extend to 4 to 8 hours (Table 86-3). When used in the inpatient setting, this standard of care results in a shorter treatment duration and reduced risk for over-sedation, which allows the clinician to focus on specific therapy for alcohol use disorder. This approach is also appropriate for the outpatient setting if monitoring of signs and symptoms can be reliably performed by the patient or caregiver.[23,25]

TABLE 86-3

Dosing and Monitoring of Pharmacologic Agents Used in the Treatment of Alcohol Withdrawal

Agent/Route	Dosage Range Per Day (Unless Otherwise Noted)	Indication	Monitoring	Duration of Dosing	Level of Evidence for Efficacy*

Multivitamin oral/IV	1 tablet	Malnutrition	Diet	At least until eating a balanced diet at caloric goal	B3
Thiamine oral/IV	100 mg	Deficiency	CBC, WBC, nystagmus	Empiric for 5 days. More if evidence of deficiency	B2
Crystalloid fluids IV (NS or D5-0.45 NS with 20 mEq [mmol] of KCl per liter)	50-100 mL/hour	Dehydration	Weight, electrolytes urine output, nystagmus if dextrose	Until intake and outputs stabilize and oral intake is adequate	A3
Clonidine oral (Catapres)	0.05-0.3 mg Consider dose reduction in older individuals	Autonomic tone rebound and hyperactivity, hypertensive urgency	Shaking, tremor, sweating, blood pressure	3 days or less	B2
Clonidine transdermal (Catapres-TTS)	TTS-1 to TTS-3 Consider dose reduction in older individuals	Autonomic tone rebound and hyperactivity	Shaking, tremor, sweating, blood pressure	1 week or less. One patch only	B3
Haloperidol oral/IV (Haldol)	2.5 to 5 mg every 2-4 hours	Agitation unresponsive to benzodiazepines, hallucinations (tactile, visual, auditory, or otherwise), or delusions	Subjective response plus rating scale (CIWA-AR or equivalent), ECG	Individual doses as needed	B1
Antipsychotics, second generation		Agitation unresponsive to benzodiazepines, hallucinations, or delusions in patients intolerant of first-generation antipsychotics	Subjective response plus rating scale (CIWA-AR or equivalent)	Individual doses as needed in addition to scheduled antipsychotic	C3
Quetiapine oral (Seroquel)	25-200 mg; dosage adjustment is necessary in hepatic impairment				
Aripiprazole oral (Abilify)	5-15 mg				
Benzodiazepines					
Lorazepam oral/IV/IM (Ativan)	0.5-8 mg	Tremor, anxiety, diaphoresis, tachypnea, dysphoria, seizures	Subjective response plus rating scale (CIWA-AR or equivalent)	Individual doses as needed. Underdosing is more common than overdosing	A2
Chlordiazepoxide oral (Librium)	25-300 mg				
Diazepam oral/IV/IM (Valium)	5-40 mg				

Oxazepam oral (Serax) oral	15-30 mg				
Dexmedetomidine IV (Precedex)	0.2 mcg/kg/hr, titrate based on response	Adjunct to BZD for autonomic hyperactivity, sympathetic symptom control	Tremor, blood pressure, heart rate	5 days or less	B2
Phenobarbital oral/IV (Luminal)	30-260 mg	Adjunct to BZD, promotes BZD binding to $GABA_A$ receptor	Sedation, respiratory depression, blood pressure	5 days or less	B2
Alcohol oral/IV		Prevent withdrawal	Subjective signs of withdrawal	Wide variation	C3

*Strength of recommendations, evidence to support recommendation: A, good; B, moderate; C, poor.

Quality of evidence: (1) evidence from more than one properly randomized controlled trial; (2) evidence from more than one well-designed clinical trial with randomization, from cohort or case-control analytic studies or multiple time series, or dramatic results from uncontrolled experiments; and (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

CBC, complete blood count; CIWA-Ar, Clinical Institute Withdrawal Assessment for Alcohol, revised; D5, dextrose 5%; ECG, electrocardiogram; KCl, potassium chloride; NS, normal saline; WBC, white blood cell count.

Fixed-Dose Therapy

Although benzodiazepines given regularly at fixed dosing intervals and subsequently tapered off have been highly effective for alcohol withdrawal, additional medication may be needed for breakthrough withdrawal symptoms. With this approach, monitoring for excessive sedation and respiratory depression is still important. Due to the administration of medication regardless of symptoms, fixed-dose therapy could be preferred in patients with a history of seizures or DT, although there is a lack of evidence to determine superiority over symptom-triggered therapy.[19,23]

Treatment of Severe Alcohol Withdrawal

The progression of symptoms to include seizures and/or DT describes severe alcohol withdrawal, where patients are often refractory to benzodiazepines and require aggressive treatment in a closely monitored setting. For hospitalized patients, the Prediction of Alcohol Withdrawal Severity Scale (PAWSS) can be used to assess the risk of developing severe or complicated alcohol withdrawal. The PAWSS tool is a questionnaire that incorporates patient responses and clinical evidence to assess severity, with a score of 4 or greater pointing toward a high risk of moderate to severe alcohol withdrawal. For patients with severe alcohol withdrawal (CIWA-Ar greater than 19), front-loading therapy with a benzodiazepine is recommended as a first-line treatment followed by phenobarbital. With close monitoring, phenobarbital can be utilized as either adjunctive therapy for patients not responding to high doses of benzodiazepines or alternative therapy if benzodiazepines are contraindicated.[19,25,26]

Alcohol withdrawal seizures do not require treatment with an antiseizure medication, such as phenytoin, unless they progress to status epilepticus or unless there is an underlying concomitant seizure disorder. In general, patients experiencing seizures, and/or experiencing resistant alcohol withdrawal, should be treated supportively under institutional/hospital-specific protocols. These patients should be closely monitored in an intensive care unit in case intubation and mechanical ventilation become necessary. For those requiring escalating doses of benzodiazepines, adjunctive therapy options to manage refractory withdrawal symptoms might include propofol with mechanical ventilation, dexmedetomidine, or ketamine.[19,25,26]

Treatment of Nutritional Deficits and Electrolyte Abnormalities

Supportive care is critical in the management of alcohol withdrawal. Fluid status, electrolyte, and vitamin abnormalities should be carefully assessed and corrected in all patients undergoing alcohol withdrawal. Hydration is necessary in patients with vomiting, diarrhea, increased body temperature, or severe agitation. Electrolyte imbalances, such as hypokalemia, hypomagnesemia, and hypophosphatemia, can often be seen because of inadequate nutrition and fluid volume related to antidiuretic hormone inhibition. Hypokalemia can be corrected with oral potassium supplementation as long as renal function is adequate. Thiamine (vitamin B1) is often depleted and can lead to decreased absorption of glucose. Thiamine deficiency should be addressed prior to glucose administration to prevent the development of Wernicke–Korsakoff syndrome (eg, mental confusion, eye movement disorders, and ataxia [poor motor coordination]). In practice, thiamine is usually given 100 mg once daily orally, IV, or intramuscularly for 3 to 5 days for prophylaxis; higher doses are utilized for acute treatment of Wernicke's encephalopathy. Additionally, patients also benefit from a daily multivitamin with folate due to poor nutritional status (see Table 86-4).[23,26]

Alcohol hypoglycemia was first described 60 years ago and usually occurs in the absence of overt liver disease. It is more likely to occur if the patient is fasting, exercising, or is sensitive to alcohol, and it is less likely if the patient is obese. Mechanistically, this occurs as alcohol directly interferes with hepatic gluconeogenesis, but not glycogenolysis. The energy required for alcohol metabolism is diverted away from the energy needed to take up lactate and pyruvate—substrates for gluconeogenesis. So, those who drink alcohol can become hypoglycemic once glycogen stores are depleted. Neurologic symptoms of hypoglycemia can be confused with alcohol intoxication, and in the inpatient setting, blood glucose should be monitored regularly.[28]

In general, alcohol withdrawal treatment can take place in hospitals, inpatient detoxification units, or outpatient settings. Only patients with mild-to-moderate symptoms should be considered for outpatient treatment, and it is a good idea to have a responsible, non-using person available to help the patient monitor symptoms and administer medications. Patients with a strong craving for alcohol, who concurrently use other substances, who have severe psychiatric problems (ie, suicidal ideations, psychosis), and/or who have a history of seizures or DT, are not good candidates for outpatient treatment. Pharmacologic agents used in the treatment of alcohol withdrawal are summarized in Table 86-4.[23,27,29]

TABLE 86-4

Dosing and Monitoring of Pharmacologic Agents Used in the Treatment of Unhealthy Alcohol Use

Medication	Dosage Range Per Day	Indication	Monitoring	Level of Evidence for Efficacy*
Disulfiram (Antabuse)	125-500 mg; use with caution in patients with hepatic disease or insufficiency	Deterrence	Facial flushing, liver enzymes	B2
Acamprosate (Campral)	999-1,998 mg and higher (333 mg tablets)	Craving	Patient-reported craving, renal function	A1
	Dosage adjustment necessary in renal impairment			
Naltrexone (ReVia)	50-100 mg; dosage adjustment may be needed in renal and liver impairment	Craving	Patient-reported craving, liver enzymes	A1
Naltrexone (Vivitrol)	380 mg intramuscularly once every 4 weeks	Craving	Patient-reported craving, liver enzymes, injection site reactions	B2
Antiseizure Medications (eg, topiramate [Topamax], carbamazepine [Tegretol], valproic acid [Depakote], gabapentin [Neurontin], oxcarbazepine [Trileptal])	Seizure disorder doses	Craving	Patient-reported craving, plasma medication levels	B2
Antidepressants (eg., fluoxetine [Prozac], amitriptyline [Elavil], citalopram [Celexa], sertraline [Zoloft])	Depression doses	Craving, depression, anxiety	Patient-reported craving	B2

*Strength of recommendations: A, B, and C, good, moderate, and poor evidence to support recommendation, respectively.

Quality of evidence: (1) evidence from more than one properly randomized controlled trial; (2) evidence from more than one well-designed clinical trial with randomization, from cohort or case-control analytic studies or multiple time series, or dramatic results from uncontrolled experiments; and (3) evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

Treatment of Alcohol Use Disorder

Nonpharmacologic Therapy

In alcohol use disorder, psychosocial interventions proven to be beneficial include motivational enhancement therapy, family therapies, cognitive behavioral therapy, behavioral approaches, and 12-step programs, such as Alcoholics Anonymous. The combination of a psychosocial intervention and pharmacologic therapy for alcohol use disorder can help reduce the frequency of drinking and the risk of binge drinking.[30]

Pharmacologic Therapy

④ In the United States, disulfiram, naltrexone, once-monthly injectable extended-release naltrexone, and acamprosate are the only four medications FDA approved for the treatment of alcohol use disorder. Disulfiram acts as a deterrent to the resumption of drinking, and naltrexone is a competitive opioid antagonist that has been shown to reduce cravings for alcohol. Acamprosate is a GABAergic agonist that modulates alcohol cravings (Table 86-4). Other medications, including nalmefene, baclofen, bupropion, various serotonergic agents (including selective serotonin reuptake inhibitors and serotonin-3 [5-HT3] receptor antagonists), topiramate, gabapentin, and varenicline, have also been used off-label in the United States or abroad for alcohol use disorder. A Cochrane review[31] of 25 trials with 2,641 patients evaluated a variety of antiseizure medications, including gabapentin, topiramate, oxcarbazepine, valproate, levetiracetam, pregabalin, zonisamide, and carbamazepine, to determine efficacy in the treatment of alcohol use disorder. Overall, these agents did perform better than placebo when comparing the number of drinks per day and average heavy drinking days, but there was insufficient evidence that these agents resulted in increased alcohol abstinence rates. The conclusion was there is insufficient evidence of efficacy to support the use of antiseizure medications in alcohol use disorder.[31] A recent meta-analysis of seven randomized controlled trials found that topiramate had moderate benefits on the number of abstinence days and frequency of heavy drinking. Of the antiseizure medications, topiramate appears to decrease alcohol consumption and is increasingly prescribed off-label as a treatment of AUD.[32]

For moderate-to-severe AUD, the American Psychiatric Association's (APA) practice guideline recommends (1) naltrexone or acamprosate to reduce alcohol consumption or achieve abstinence or (2) disulfiram for patients who have not responded to naltrexone and acamprosate and who understand the potential adverse effects with concurrent alcohol intake. Additionally, the APA also recommends gabapentin or topiramate in moderate-to-severe AUD, for patients who prefer one of these medications or who are intolerant of or who have not responded to the FDA-approved agents.[33]

Disulfiram

Disulfiram was the first FDA-approved medication for alcohol use disorder. It deters a patient from drinking by producing an aversive reaction if alcohol is consumed; otherwise, it has minimal effects. Pharmacologically, it inhibits aldehyde dehydrogenase in the biochemical pathway for alcohol metabolism, allowing acetaldehyde to accumulate. If a patient consumes alcohol within 12 to 24 hours of taking disulfiram, the resulting increase in acetaldehyde causes severe facial flushing, throbbing headache, nausea and vomiting, chest pain, palpitations, tachycardia, weakness, dizziness, blurred vision, confusion, and hypotension, referred to as a "disulfiram reaction." In severe (rare) cases, the reaction can lead to myocardial infarction, congestive heart failure, cardiac arrhythmia, respiratory depression, convulsions, and death, particularly in vulnerable individuals. When disulfiram is prescribed, abstinence from alcohol is a critical component of patient education and supervision is recommended to promote adherence.[20,33] Evidence in a meta-analysis of 22 randomized trials found that, in 17 open-labeled studies, disulfiram was associated with a higher abstinence benefit compared with controls; blinded studies did not demonstrate a benefit.[34]

Naltrexone

Naltrexone, a potent opiate antagonist, is available for the treatment of unhealthy opioid use as it blocks the effects of exogenous opioids (for more details, see Chapter 85, "Substance Use Disorders I: Opioids, Cannabis, and Stimulants"). It is also FDA approved for the treatment of unhealthy alcohol use, and it is thought to attenuate the reinforcing effects of alcohol. Those who consume alcohol while taking naltrexone report feeling less intoxicated and having fewer alcohol cravings.[4,29] Evidence suggests that genetics play a role in the clinical response to naltrexone, and its efficacy varies greatly among individuals. In previous preliminary studies, the Asn40Asp (118A>G, A355G, rs1799971) polymorphism in the μ-opioid receptor gene (*OPRM1*) demonstrated an increased response to naltrexone with lower rates of relapse to heavy drinking; however, a recent controlled clinical trial disputed these results,[35] and further studies are ongoing.

Naltrexone administration does not induce alcohol withdrawal; however, it should not be given to patients currently receiving opiates because it will block their therapeutic effects and can precipitate severe opioid withdrawal syndrome. Naltrexone should be used with caution in patients with moderate-to-severe renal impairment and baseline liver function tests (LFTs) are recommended. Current evidence supports the tolerability of naltrexone in high-risk patients with hepatitis C and human immunodeficiency virus (HIV). When initiating naltrexone, the patient should not be in acute alcohol withdrawal and should be involved in psychosocial treatment.[33,36] A review of 50 randomized controlled studies,[37] which included 7,793 patients, found that oral naltrexone decreased drinking days by 4% and decreased the risk of heavy drinking by 83% compared to placebo. The most common adverse effects were nausea and daytime sedation. The usual starting dose of oral naltrexone is 50 mg/day, but doses of 100 mg/day have been used.[37]

In April 2006, the FDA approved Vivitrol, a once-monthly intramuscular naltrexone formulation, given at a dose of 380 mg that can be administered in an outpatient setting.[36]

Extended-release formulations reduce the likelihood of forgetting or choosing not to take the medication, ensuring medication adherence for the next month. However, the cost is considerably higher than the oral formulation.[36]

The extended-release form of naltrexone may be more beneficial in reducing heavy drinking rather than abstinence. In a recent meta-analysis of seven randomized, double-blind trials, all requiring abstinence before treatment, extended-release naltrexone resulted in two fewer drinking days and one to two fewer heavy drinking days per month compared to placebo. Larger reductions in heavy drinking were reported in trials that did not require abstinence prior to study enrollment and that lasted longer than three months.[38]

Acamprosate

Acamprosate is a glutamate modulator at the *N*-methyl-D-aspartate receptor that reduces alcohol craving. Individuals treated with acamprosate are more successful in maintaining abstinence from alcohol versus placebo. Acamprosate is well tolerated, with GI adverse effects being the most common. It is not metabolized through the liver but is excreted through the kidneys and should be used with caution in individuals with severe renal dysfunction by making appropriate dose adjustments.[29,33]

A Cochrane review of 24 randomized controlled trials with 6,915 participants[39] found that acamprosate significantly reduced the risk of any drinking and significantly increased the cumulative abstinence duration (mean difference 10.94 days) compared to placebo. Diarrhea was the only adverse effect more frequently reported with acamprosate than placebo.

TABLE 86-5 includes the dosing information for acamprosate and other options used in treating alcohol use disorder.[20,29,30] When selecting a medication for an individual patient, factors such as ease of administration, available formulations, renal or hepatic disease, pregnancy, adverse effects, presence of co-occurring conditions, or specific symptoms of AUD should guide medication therapy decisions. Duration of treatment is dependent on several patient-specific factors, such as clinical response, tolerability, patient preference, history of relapses, and severity of the disorder.[23]

TABLE 86-5

US Preventive Services Task Force (USPSTF) Interventions for Tobacco Smoking Cessation in Adults, Including Pregnant Persons: Summary Table

Population	Adults >18 Years Old (Nonpregnant)	Pregnant Persons >18 Years Old
Assessment	Screen for all tobacco Consider the following approaches: ○ 5As ○ Ask Assist Refer ○ Use smoking status as a vital sign	Screen for all tobacco Consider the following approaches: ○ 5As ○ Ask Assist Refer ○ Use smoking status as a vial sign ○ Consider using a multiple choice question approach during assessment to improve comfort level
Behavioral interventions	• In person behavioral support and counseling >4 sessions which each session averaging 90-300 minutes (group/individual option) ○ Efficacy improves with 8 sessions or more • Telephone counseling/mobile phone based interventions (>3 sessions)	• Counseling • Self help materials • Feedback • Health education • Incentives • Social support
Pharmacotherapy	• NRT • Bupropion SR • Varenicline • +/-Behavioral interventions • Combination of NRT (long acting + short acting NRT demonstrated higher efficacy vs. single NRT approach)	• Inadequate evidence due to lack of studies to determine benefit vs risk
Comments on benefits and harms	Conclusion from USPSTF; behavioral interventions and +/− pharmacotherapy interventions with FDA-approved pharmacotherapy agents for smoking cessation demonstrated substantial benefit	Conclusion from USPSTF; behavioral interventions demonstrated substantial benefit for perinatal outcome and improved smoking abstinence
Electronic nicotine delivery systems (electronic cigarettes)	Evidence on the use of ENDS for tobacco cessation is insufficient, benefit vs risk cannot be determined	Evidence on the use of ENDS for tobacco cessation is insufficient, benefit vs risk cannot be determined

ENDS, Electronic Nicotine Delivery Systems; FDA, Food and Drug Administration; NRT, Nicotine Replacement Therapy.

Data from Reference 10

EVALUATION OF THERAPEUTIC OUTCOMES

Considering the increasing rates of alcohol use and the variable effects of alcohol from individual to individual, screening tools such as the CAGE questionnaire and AUDIT are instrumental in detecting unhealthy alcohol use and identifying those at risk for alcohol withdrawal. Treating alcohol withdrawal takes precedence over the treatment of alcohol use disorder. The assessment of alcohol withdrawal begins with utilizing the CIWA-Ar to assess withdrawal symptom severity before initiating pharmacologic therapy with benzodiazepines. Close monitoring is essential to avoid progression to severe withdrawal, which includes seizures and/or DT.

For alcohol use disorder, both psychosocial interventions and pharmacologic therapy can be beneficial to reduce drinking frequency. Four agents have FDA approval for the treatment of alcohol use disorder. Careful consideration of patient-specific factors needs to be done, as each agent works pharmacologically different to reduce cravings (acamprosate and extended-release naltrexone) or act as a deterrent to the resumption of drinking (disulfiram). Patient counseling on potential adverse effects followed by close monitoring and follow-up are necessary to assess response to therapy and promote adherence.

INTRODUCTION—NICOTINE

5 Annually, approximately 480,000 deaths in the United States are attributable to tobacco use, making smoking the leading cause of preventable death and disease in the United States.[40–42] Adverse health effects of tobacco use impact almost every organ in the body and can result in an increased risk of cancer, respiratory disease, and cardiovascular disease, as well as negatively impacting the immune system and reproductive health. Over 16 million Americans currently suffer from diseases directly related to smoking.[41,43]

The number of individuals who smoke cigarettes has continued to decline over the years. In 2019, the National Health Interview Survey reported 14% or 34.1 million of adults smoked cigarettes, which is reduced from the 42% reported in 1964, when the first Surgeon General's report on smoking was released.[44]

Although smoking cigarettes is still the most popular method of tobacco exposure,[10] a small percentage of individuals use alternative forms of nicotine products such as cigars (3.6%), pipes (1%), smokeless tobacco (2.4%), and e-cigarettes (4.5%).[44] It is important to recognize the downward trend in the percent of individuals who smoke cigarettes is not uniform across all populations in the United States. In order to reduce the disparities seen in tobacco use, continued education for healthcare providers is needed. Behavioral and pharmacotherapy interventions have proven effective and these are supported by the clinical guidelines for tobacco use and use disorder as outlined in Fig. 86-1.[10]

There have been numerous approaches to smoking cessation, including a focus on sales, marketing, and manufacturing of all tobacco products marketed in the United States thatare now regulated by the FDA. Federal tobacco excise taxes have increased, and states have also added cigarette excise tax rates. Additionally, many states have enacted comprehensive smoke-free laws, and further opportunities for access to smoking cessation pharmacotherapy and counseling are available through the Affordable Care Act.[41,45]

National telephone quitlines, smoking cessation counseling services, and mass media campaigns have been utilized to improve smoking cessation rates. “Tips from Former Smokers” was a successful federally funded national mass media antismoking campaign,[46,47] and various internet and mobile phone text messaging programs have been developed over the years. The QuitGuide Mobile App is a free app released by Smokefree.gov, which provides resources to track craving patterns and motivation, and monitors progress as milestones are achieved.[48] Despite the proven effectiveness of pharmacological and counseling services to aid in sustained smoking cessation, cigarette smoking continues to be the leading cause of preventable morbidity and mortality in the United States.[41]

EPIDEMIOLOGY

The National Survey on Drug Use and Health (NSDUH) reported in 2017 that an estimated 58.1 million people (21.1%) had exposure to a tobacco product at least once in the month prior to being interviewed. Additionally, 45.9 million of the US population age 12 and older currently smoke cigarettes, defined as smoking at least a part of the cigarette. Of these, 58.4% were daily smokers (26.8 million) and 40.5% (10.8 million) reported smoking a pack or more of cigarettes per day.[3] In addition, 11.7 million smoked cigars, 8.5 million used smokeless tobacco, and 1.9 million smoked pipe tobacco.[3] Comparing age groups, data from 2019 demonstrated adults 26 years and older have the highest rate of daily cigarette use (62.5%). In contrast, adolescents 12 to 17 years of age reported the lowest daily cigarette use in the month (13.2%). This data from 2019 shows that each age group has reported lower percentages of daily cigarette use compared to the early 2000s, although the percentages in recent years have been fairly similar. The downward trend over the last two decades is encouraging but continued tobacco cessation education is needed. Importantly, this report has not included vaping of nicotine products; however, tracking of trends in the use of nicotine vaping products is ongoing.[3]

Additional data has been provided in the Population Assessment of Tobacco and Health (PATH) Study launched in 2011. This household-based longitudinal cohort study is a collaboration between the FDA Center for Tobacco Products, the National Institute on Drug Abuse (NIDA) and the National Institutes of Health (NIH), which include youths age 12 to 17 years old and adults. Overall 45,000 current tobacco users and nonusers in the United States were included to help evaluate tobacco use and its effects on overall health.[49,50] The PATH study differs from NSDUH since the assessment includes biomarker collection, a detailed assessment of tobacco-use behaviors, and further detailed examination of specific tobacco products to distinguish between them and ensure clarity in usage patterns.[51] The goals of this study are to determine what products are commonly used including the use of e-cigarettes; factors associated with susceptibility of use; evaluate patterns of use; review the overall health impacts associated with smoking, smoking cessation, and relapse; and identifying any racial/ethnic, gender, and age differences in use.[51]

The Wave 1 data, collected from September 2013 through December 2014, indicated that more than 25% of adults used one type of tobacco product during this time period. Approximately 9% of youth used a tobacco product in the last 30 days, and 1.6% of these were daily users of tobacco. Forty percent of the respondents indicated they were using multiple tobacco products at the same time, with the most common combination being cigarettes and e-cigarettes together. The PATH Study also found that in adults, tobacco use is higher in males, members of racial minority groups, and individuals who have lower household incomes or lower education levels.[51]

However, tobacco-related health disparities (TRHD) have been identified in many patient populations.[52] In addition to those reported in in the PATH study, individuals with mental health conditions, and substance use disorders also have higher rates of tobacco use.[10] Additionally, certain geographic locations in the United States have been identified as having a higher prevalence of cigarette smoking, including the Midwest and South compared to the Northeast and West. The prevalence of cigarette smoking is higher the lesbian, gay, bisexual, transgender, and queer (LGBTQ+) population in both adults and youth. Further study on tobacco-related health disparities is needed to continue to develop guidelines and policies on how to effectively identify and reduce disparities, inequities, and inequalities to improve overall care and continue to improve the tobacco cessation rates.[41]

Economic Impact of Smoking

The yearly direct healthcare expenditures associated with smoking for adults is estimated at nearly $170 billion for direct medical care and $156 billion in indirect costs, such as lost productivity.[43,53] Included in these costs are the estimated $39 billion annually for Medicaid patients. This number is significant, as this small subset of the population has higher smoking rates compared to privately insured patients.[54]

Health Risks of Smoking

Cigarette smoking greatly increases the risk of (a) cardiovascular diseases such as stroke, sudden death, and heart attack; (b) nonmalignant respiratory diseases including emphysema, asthma, chronic bronchitis, and chronic obstructive pulmonary disease; (c) lung cancer and other cancers, (d) diabetes, and (e) harmful effects to reproductive health, including erectile dysfunction.[40,43] Exposure to environmental tobacco smoke (*passive exposure and secondhand smoke*) has been cited as the cause of lung cancer, stroke, and coronary heart disease in adults.[55] Children who are exposed to environmental smoke have a higher risk of heart disease, respiratory infections, asthma, and ear infections than those not exposed.[55] Sudden infant death syndrome (SIDS) occurs more often in infants whose mothers smoked during pregnancy compared to offspring of nonsmoking mothers. Studies continue to determine how environmental smoke can increase the risk of SIDS. Additionally, long-term adverse negative cardiovascular consequences have been identified in children exposed to environmental smoke leading to an increased risk of cardiovascular complications later in life.[56]

PATHOPHYSIOLOGY

Nicotine is an agonist at nicotinic acetylcholine receptors (nAchRs) with pharmacologic effects highly dependent on dose. These effects include central and peripheral nervous system stimulation and depression, respiratory stimulation, skeletal muscle relaxation, catecholamine release by the adrenal medulla, peripheral vasoconstriction, and increased blood pressure, heart rate, cardiac output, and oxygen consumption. Cigarette smoking or low doses of nicotine produce an increased alertness and increased cognitive functioning by stimulating the cerebral cortex. At higher doses, nicotine stimulates dopamine within the “reward” center in the brain’s limbic system.[57] When nicotine is ingested, a feeling of pleasure and relaxation can occur. Repetitive exposure to nicotine leads to neuroadaptation, which builds tolerance to the initial effects. An accumulation of nicotine in the body leads to a more substantial withdrawal reaction if cessation is attempted. Common symptoms experienced during withdrawal can include anxiety, difficulty concentrating, irritability, and strong cravings for tobacco.[58] Onset of these withdrawal symptoms usually occurs within 24 hours and can last for days, weeks, or longer. Additionally, some might experience a state of malaise or inability to experience pleasure during this nicotine withdrawal period. These types of reactions have been termed “hedonic dysregulation” and can be rapidly reversed with nicotine readministration.[59] This powerful force of nicotine effects leading to physical dependence is one reason smokers attempting smoking cessation have a high rate of relapse, and only 3% remain abstinent 6 months following the quit date.[60]

The genetics associated with nicotine addiction is very complex and continues to be studied with great interest. Progress continues to be made in understanding the human genome and identifying more specific markers for various diseases. Many phenotypes and corresponding genes have been identified as markers, which include the genetic markers, nicotinic cholinergic receptor alpha5 subunit (CHRNA5) and cytochrome P450 2A6 (CYP2A6), and the metabolic marker, nicotine metabolism ratio (NMR). All three of these have been found to have a relationship with smoking behavior, including nicotine physical dependence and cigarettes per day. Additionally, the CHRNA5-CHRNA3-CHRNB4 locus has been found to predict lung cancer, chronic obstructive pulmonary disease (COPD), coronary artery disease, and mortality.[61,62] Having the ability to identify patients at higher risk can improve chances of diagnosing cancer earlier in the disease process so treatment can begin sooner and improve prognosis.[61]

Studies continue to evaluate the effects of polymorphisms on various genes and the effect this has on the efficacy of pharmacotherapy treatment options in order to offer options for more personalized treatment in the future.[62] Genetic variability in nicotine metabolism continues to be evaluated since variations in CYP2A6 lead to different rates of nicotine physical dependence and responses to NRT.[61] Further understanding of these variations will continue to prove helpful in creating a personalized pharmacotherapy plan to improve smoking cessation rates.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Nicotine Withdrawal

General

- The patient may experience anxiety, but may not be in acute distress. Symptoms can wax and wane over time.

Symptoms

- The patient may complain of cravings, difficulty concentrating, frustration, irritability, and impatience. Hostility, insomnia, and restlessness can also occur.
- Increased skin temperature can be present.

TREATMENT

Desired Outcomes

Ideally, the desired outcome is for all tobacco users to quit, and that young people never take up the habit. Unfortunately, this is unlikely to happen. The Healthy People 2030 target has set a goal prevalence of tobacco use at less than or equal to 16.2% in adults 18 years and older. This is a realistic and believed to be an achievable goal since the National Health Interview Survey 2018 figures have reported at 20.1% of adults use any tobacco product, as well as continued declines in the percent of the adult population who smoke cigarettes.[44,63]

Nicotine physical dependence: Recognition of Behavior

⑥ The United States Preventive Services Task Force (USPSTF) released the "Interventions for Tobacco Smoking Cessation in Adults, Including Pregnant Persons in 2021."[10] This recommendation stresses that all healthcare providers should ask each adult about tobacco use, advise any adult using tobacco to stop using, and provide behavioral inventions and pharmacotherapy options to aid in smoking cessation (Fig. 86-2). These recommendations also included pregnant individuals and are summarized in Table 86-5. Additional information regarding the challenges of pharmacotherapy treatment options for smoking cessation in pregnant persons is also available.[10]

A well-established method of assessing an individual's smoking status utilizes the 5As as follows:[10]

1. **A**sk about tobacco use
2. **A**dvise the person to quit through clear individualized messages
3. **A**ssess the person's willingness to quit
4. **A**ssist in quitting
5. **A**rrange follow-up and support

Other approaches recommend using the "Ask, Advise, Refer" approach or recording the patient's smoking status as a vital sign during each appointment. The USPSTF statement expanded on the 5As and recommended that for pregnant individuals a higher comfort level was demonstrated if these questions were asked in a multiple-choice format instead of open-ended questions.[10] Additionally, another approach includes the "Ask, Advise, Refer," which can be used to assist individuals in obtaining access to smoking cessation services.

The Fagerström test for nicotine physical dependence can be used to help identify how much someone is smoking, the compulsion to use, and the level of physical dependence. This instrument includes questions that can be answered as either yes or no. Each question answered as yes is worth 1 point. The scoring is 0 to 10; the higher the score, the higher the individual's physical dependency to nicotine.[64] When assessing for tobacco use and approaching tobacco cessation counseling, there might be times when someone is not ready to consider an attempt tobacco cessation. A motivational intervention to consider is the 5R's.[65]

- Relevance: Discuss possible reasons why tobacco cessation is personally relevant.
- Risks: Explore the individual's views of potential risks and negative consequences of tobacco use.
- Rewards: Explore what positive benefits could result in tobacco cessation
- Roadblocks: Encourage the individual to identify and voice potential benefits of tobacco cessation.
- Repetition: Commit to address tobacco cessation during each interaction and continue to encourage those who have previously failed attempts.

Nonpharmacologic Therapy

The USPSTF statement emphasized the importance of counseling sessions and highlighted the goal of reaching at least four in-person sessions, with a total contact time ranging from 90 to 300 minutes.[10] A Cochrane analysis reviewed 65 trials, which included approximately 23,000 patients, who received a combination of pharmacotherapy treatment and behavioral support either in person or through telephone interaction. This review determined that the addition of behavioral support improves the smoking cessation efforts by 10% to 20%.[66] Although comprehensive behavioral interventions have been shown to be more effective in helping people quit smoking and remain abstinent, less intensive treatments may be beneficial as well. Even minimal contacts lasting less than 3 minutes, which include the 5As, are more successful in increasing cessation rates than an intervention involving no contact.[41]

Motivational interviewing is a collaborative approach to help patients identify barriers for making a behavior change. A meta-analysis of 37 studies, including over 15,000 smokers undergoing motivational interviewing (MI) compared the efficacy of both intensive MI and less intensive MI to no treatment, other smoking cessation treatments, and other types of smoking cessation treatments. Overall, MI is moderately effective in increasing the chances of long-term smoking cessation when utilized with other smoking cessation treatment approaches and when compared to other treatment approaches without the MI approach. However, there was insufficient evidence to determine if MI improves smoking cessation when compared with no treatment. Further research is needed to continue to evaluate the efficacy of MI.[67]

Additionally, other forms of interventions are effective in improving smoking cessation rates. Telephone-based quitlines, which are operated by the National Cancer Institute and offered in all 50 states, the District of Columbia, Puerto Rico, and Guam via 1-800-QUIT-NOW, provide various options, such as recorded messages, counseling services, mailed materials, counselor follow-up services, and access to pharmacotherapy options for smoking cessation.[68] Along with continued support and monitoring of state quitlines, the Centers for Disease Control and Prevention (CDC) has now established the National Quitline Data Warehouse (NQDW) for continual evaluation and support of services.[69] The use of technology to further enhance counseling opportunities has also increased over the years, including websites, text messaging, social networking, and smartphone applications. A systematic review and meta-analysis evaluated 26 manuscripts that included over 33,000 smokers who received text messages for smoking cessation. Overall patients receiving the text messages were much more likely to achieve smoking cessation by 50% to 60%.[70]

Furthermore, while counseling alone can be effective, its efficacy is further augmented by the addition of pharmacotherapy, with NRT also being effective independent of counseling services.[10] The combination of pharmacotherapy and behavioral interventions were evaluated in different subpopulations, including ethnic minorities and patients suffering from mental health conditions. No evidence was found suggesting there was a difference in risk or benefit of this treatment approach within these populations.[41]

Pharmacologic Therapy

Pharmacologic therapy helps facilitate the process of tobacco cessation by the following mechanisms:[71]

1. “Reducing nicotine withdrawal symptoms”

2. “Reducing the rewarding effects of nicotine from smoking by blocking or desensitizing nicotine receptors”

3. “Providing an alternative source of nicotine with the desired pharmacologic effect previously provided by nicotine from cigarettes””

All patients attempting to quit should be encouraged to use effective pharmacotherapy agents for smoking cessation except in the presence of special circumstances or contraindications. For pregnant individuals, the USPSTF statement recommends that clinicians weigh the benefits and the harms associated with pharmacotherapy interventions and treat each patient on an individual basis.[10] Current recommendations list seven first-line agents including the NRT medications, sustained release bupropion hydrochloride, and varenicline tartrate as treatment options.[10,41] First-line therapy options in smoking cessation are summarized in Table 86-6.[41,72–79]

TABLE 86-6

First-Line Pharmacotherapy Treatment Options for Smoking Cessation

Medication	Dosing (For individuals 18 years or older. For those <18 years, discuss with a prescriber before use)	Duration	Comments/Monitoring Parameters
Nicotine Replacement Therapies (NRTs)			
Nicotine patch	Based on cigarettes smoked per day: **>10 cigs/day:** Step 1: 21mg/day: Weeks 1-6 Step 2: 14mg/day: Weeks 7-8 Step 3: 7mg/day: Weeks 9-10	8-10 weeks	• Patch can be worn for up to 24 hours per day ○ If patient has sleep disturbances, remove patch at night and place one patch in morning (~16 hours per day) ○ If waking up with cravings, patch should be worn for 24 hours • Recommended to place patch on stop day. However, if patient smokes with patch on, there is no major risk • Place a new patch on each day, hold patch on for 10 seconds to help adherence • Rotate patches to avoid skin irritation • Do not cut patches, do not wear patches for greater than 24 hours, do not use more than one patch at a time
	<10 cigs/day: Step 2: 14mg/day: 6 weeks Step 3: 7mg/day: 2 weeks		

Nicotine gum	1st cigarette ≤ 30 minutes after waking: 4 mg 1st cigarette ≥ 30 minutes after waking: 2 mg Weeks 1-6: 1 piece of gum every 1-2 hours prn Weeks 7-9: 1 piece every 2-4 hours prn Weeks 10-12: 1 piece every 4-8 hours prn Then stop Do not exceed 24 pieces/day	12 weeks	• Continuous use can lead to adverse effects (pyrosis, nausea, hiccups) • 4 mg strength has shown to be more efficacious in heavy smokers over 6-week time period • If patient uses with a cigarette, there is no major risk • Counseling on proper use of gum: ○ Do not eat or drink 15 minutes before or during use of gum ○ Chew each piece slowly ○ Park between cheek and gum after a peppery sensation becomes apparent ○ Repeat process until peppery sensation does not reoccur (approximately 30 minutes) ○ Use alternate sides of mouth when using chew and park method ○ Use at least 9 pieces of gum per day for first 6 weeks to improve cessation
Lozenge available as Nicorette lozenge or Nicorette mini lozenge	1st cigarette ≤ 30 minutes after waking: 4 mg 1st cigarette ≥ 30 minutes after waking: 2 mg Weeks 1-6: 1 lozenge by mouth every 1-2 hours prn Weeks 7-9: 1 lozenge by mouth every 2-4 hours prn Weeks 10-12: 1 lozenge by mouth every 4-8 hours prn Then stop Do not exceed 5 lozenges in 6 hours or 20 lozenges/day	12 weeks	• Counseling points ○ Do not eat or drink anything 15 minutes prior to or during lozenge use ○ Allow the lozenge to dissolve slowly, approximately 20-30 minutes ○ Nicotine release could create a tingling or warm sensation ○ Do not chew or swallow the lozenge ○ Periodically rotate the lozenge to different areas of the mouth ○ Use at least 9 lozenges per day for first 6 weeks to improve cessation.
Nicotine oral inhaler + cartridge plus mouthpiece (Nicotrol®)	10 mg nicotine/cartridge; supplies 80 puffs 1. Stop smoking completely before use. 2. Initial dose: 1 cartridge every 1-2 hours 3. Begin gradual reduction of device after 3 months of use 4. Gradual dose taper over 6-12 weeks	6 months	• Patients should stop smoking prior to starting this product • Most successful patients in trials; use ranged from 6-16 cartridges per day, 20 minutes continuous puffing • Recommended duration of treatment: 3 months with subsequent weaning with gradual reduction over 6-12 weeks • Treatment longer than 6 months has not been studied • Precautions: patients with asthma, chronic pulmonary disease, history of recent myocardial infarction, serious arrhythmias, or worsening angina • Counseling: ○ Insert cartridge into mouthpiece and inhale medication quickly by puffing on mouthpiece for continuously for 20 minutes or four 5 minute sessions ○ Deep inhalation is not necessary when using this product

			○ Change cartridge when nicotine taste is no longer detected ○ Dosing is individualized; initially it is recommended to use at least 6 cartridges per day for 3-6 weeks. Do not exceed 16 cartridges per day.
Nicotine metered nasal spray (Nicotrol NS®)	Availed in 10mg/ml bottle 1 spray (0.5mg nicotine/spray) into each nostril 1-2 times each hour when craving cigarette Max dose: 10 sprays per hour (max of 80 sprays per day)	3-6 months	• Two sprays is considered **1 dose** • Treatment duration is 3 months; safety beyond 6 months has not been studied • Counseling: ○ Breathe normally while administering spray, do not sniff or inhale deeply while administering spray ○ Wait at least 2-3 minutes before blowing nose after using product ○ For best results, use at least 16 sprays per day which has been found as the minimum effective dose ○ Pregnancy Category D
Non-Nicotine Replacement Options			
Bupropion (Zyban)	150 mg by mouth daily × 3 days then 150 mg by mouth twice daily (dosing interval should be > 8 hours)	3-6 months	• Do not exceed 300mg/day • Recommend initiating therapy 1-2 weeks prior to set “quit” day • Tapering is not needed with discontinuing agent • Black box warning for neuropsychiatric warning and suicide warnings removed in 2016; downgraded to warning • Pregnancy category: C, excreted into breastmilk • Monitor patients with renal/hepatic impairment • Counseling points: ○ May cause dry mouth ○ May cause insomnia, avoid bedtime dosing ○ May help with post-cessation weight gain ○ Recommended dosing interval: more than 8 hours when taking twice daily
Varenicline (Chantix®)	Start with dose titration: Days 1-3: 0.5 mg by mouth once daily Days 3-7: 0.5 mg by mouth twice daily Week 2 until end of treatment: 1 mg by mouth twice daily	12 weeks; an additional 12 week course may be used in select patients	• Take with food and a full glass of water • Quit day can be flexible with 4 options: ○ Start varenicline 1 week after quit day ○ Start varenicline and establish quit day between days 8 and 35 ○ Start varenicline and gradually reduce smoking with goal of cessation by week 12 of therapy • If patient has difficulty with cessation, taper smoking by 50% each month with a goal of smoking abstinence in 12 weeks, continue varenicline for another 12 weeks for a full 24 week therapy • Maintenance up to 6 months therapy is approved

			• Renal impairment dosing for CrCl ≤ 30mL/min (0.5 mL/s) • No dosing adjustment needed in hepatic impairment • Neuropsychiatric adverse events: black box warning removed in December 2016, warning remains • Counseling Points: ○ Varenicline works in two ways by reliving symptoms of nicotine withdrawal and blocking rewards of smoking ○ Most common adverse medication effects: nausea, sleep problems, constipation, gas, vomiting ○ Consider dose reduction if experiencing insomnia

Data from References 41,72–79.

Nicotine Replacement Therapy

⑦ Nicotine replacement therapy provides lower peak levels and lower levels of nicotine concentrations compared to cigarettes, leading to reductions in the reinforcing effects of smoking. Another benefit of NRT includes the decrease and eventual elimination of exposure to the harmful substances included in cigarettes.[80] Individuals have easy access to many of these products since five of these are available over-the-counter, with only the nasal inhaler and the nasal spray currently being prescription products. A recent review showed that all the commercially available forms of NRT (eg, chewing gum, transdermal patches, nasal spray, lozenge, inhalers, and tablets) were effective for smoking cessation, increased the quit rate by 50% to 60%, and were tolerated with very limited reports of serious adverse events.[81] Combinations of these agents have been demonstrated in multiple studies and meta-analyses to improve abstinence rates in comparison to monotherapy.[10,82]

In some smoking cessation protocols, it is suggested that NRT use begins on the patient's defined quit day. However, other recommendations have suggested patients utilize the preloading approach with NRT in which patients start NRT prior to setting the quit date. It is thought the use of NRT with smoking will reduce the satisfaction associated with smoking and break the reward pattern associated with smoking. This approach can allow the patient to set the quit date when comfortable. A recent Cochrane review for 9 studies with over 4,000 patients demonstrated there is moderate evidence to support this approach in improving quit rates (RR 1.25, 95%, CI 1.08-1.44).[82]

Nicotine Gum

Nicotine gum offers a rapid onset and short duration of effect that can be very beneficial since the amount of nicotine and the timing can be controlled by the patient. The recommended dosing is based on the "time to first cigarette" (TTFC), which indicates the response to the nicotine deprivation.[83] The FDA has approved the nicotine starting doses of 4 mg for patients who experience TTFC less than 30 minutes and 2 mg for patients who experience the TTFC greater than 30 minutes.[84] Recent studies have demonstrated utilization of the 4-mg dose will increase the chances of achieving smoking cessation compared to the use of the 2-mg gum in highly dependent smokers.[82] The gum should be chewed slowly until a peppery or minty taste emerges and then "parked" between the cheek and gums to facilitate nicotine absorption through the oral mucosa. Acidic beverages (eg, coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. Instructions to chew the gum on a fixed schedule (at least one piece every 1-2 hours) for at least 1 to 3 months can be more beneficial than ad libitum use.[78] Generally, the gum should be used for up to 12 weeks with no more than 24 pieces chewed per day.[78]

Nicotine Lozenge

The nicotine lozenge is available as a 2-mg or 4-mg dose, with the lower amount recommended for patients who normally smoke their first cigarette later than 30 minutes after awakening, and the higher dose being reserved for smokers who smoke within 30 minutes of waking. It is recommended that no more than 20 lozenges should be used in one day, for up to 12 weeks. The most common adverse effect of the lozenge is nausea. As with the nicotine gum, acidic beverages (eg, coffee, juices, or soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during use of the lozenge.[75]

Nicotine Patch

The nicotine patch is available as a nonprescription medication and is the NRT option with the highest rate of adherence.[71] This nicotine product provides a steady amount of transdermal nicotine for 16 to 24 hours based on the selected product. The patch is available in three strengths and package labeling suggests individuals who smoke more than 10 cigarettes per day start with the 21 mg patch and those who smoke less than 10 cigarettes per day start with the 14-mg patch. This initial regimen will be worn for 4 to 6 weeks and then a tapering regimen will begin which includes reducing the patch strength approximately every 2 weeks.[41,77] The patch can be used up to 8 to 10 weeks per the labeling guidelines. Patients who experience sleep disruption should remove the 24-hour patch prior to bedtime or use the 16-hour patch. The patient should place a new patch on a relatively hairless location, typically between the neck and waist. The site of application should be changed daily to diminish any skin irritation from the patch adhesive. There are no restrictions on activity while using the patch.[41,77]

The patient should be told that using the patch results in less desire to smoke and provides an opportunity for a new nonsmoker to reduce their hand-mouth habit without being burdened by craving. The patient should understand that with smoking, there are naturally peaks and valleys in the amount of nicotine in the bloodstream. However, with the patch, there is a steady gradual rise in the blood nicotine concentration that levels off and remains constant for much of the day, and then gradually decreases while the person is asleep.[41] A recent Cochrane review concluded that in individuals who smoke more than 15 cigarettes per day, the 21 mg nicotine patches resulted in a higher quit rate compared to the lower 14 mg nicotine patches.[81] Combining the nicotine patch with an oral formulation, such as the nicotine gum which allows ad libitum nicotine delivery, can improve overall cessation without significant increased risk for harm.[41] In fact, various studies have evaluated combination NRTs and based on high certainty evidence, the use of a nicotine patch can be used with the nicotine gum, lozenge, or nasal spray on an as needed basis to improve the long-term quit rate compared to NRT monotherapy.[82] However, it is important to also incorporate behavioral strategies with pharmacotherapy as recommended by current guidelines.[41,79,85]

Nicotine Nasal Spray

Nicotine nasal spray is available exclusively as a prescription medication and differs from the other short-acting NRTs due to the higher peak and trough concentrations, as it is more rapidly absorbed and eliminated than other forms.[85] A dose of nicotine nasal spray consists of one 0.5 mg delivery to each nostril (1 mg total). Initial dosing should be one to two doses per hour, increasing as needed for symptom relief. The minimum recommended treatment is 8 doses per day, with a maximum limit of 40 doses per day (five doses per hour). Recommended duration of therapy is 3 months. Individuals should not sniff, swallow, or inhale through the nose while administering doses because this increases irritating adverse effects.[74]

Nicotine Oral Inhaler

The nicotine oral inhaler consists of a mouthpiece and a plastic cartridge placed into the inhaler, which delivers 4 mg or 10 mg of nicotine, through vapor inhalation. Approximately 2 mg is systemically absorbed mainly in the throat and upper airway.[71,72] It is suggested that the individual actively puff on the inhaler for 5 minutes at a time and adjust use based on effect, as the cartridge can be used for up to 20 minutes of active puffing. The recommended initial dosing is 6 to 16 cartridges per day for up to 12 weeks of therapy. Tapering of the product should start 6 weeks after initiation.[72] As the inhaler resembles a cigarette, it also provides the sensory stimulation to help decrease some of the cue-induced cravings by alleviating the hand-mouth habit.[41,71,85] However, there are some concerns this inhaler may do the opposite and possibly reinforce smoking habits.[85]

Instructing Patients in the Use of NRT

Compliance with NRT improves when individuals are presented a clear rationale for its use and realistic expectations about response. It should be explained that nicotine is responsible for physical dependence and that discontinuation causes cigarette craving, tension, irritability, sadness, problems with sleep, and difficulty concentrating. The NRT products help reduce these physical symptoms so individuals can modify behavioral and psychological aspects associated with smoking.[71] The products have relatively few adverse effects; however, nausea and light-headedness are possible symptoms of nicotine overdose that warrant a dose reduction.[10,82]

Duration

Initially, when NRT products were approved by the FDA, they were approved for 8 to 12 weeks of therapy. However more recent practice is to inform those who commit to quitting smoking than using NRT for up to 3 months is common. Additionally, some individuals will experience severe withdrawal even beyond this time period, and thus long-term use of NRT might be indicated. The long-term use of NRT 6 months or longer has not been linked to any safety concerns,[41,71] although there is still insufficient efficacy data based on a meta-analysis and further research is needed.[41,86]

Electronic Nicotine Delivery Systems

Electronic nicotine delivery systems (ENDS) (also known as e-cigarettes or electronic cigarettes, or vaping devices) are designed to deliver a propylene glycol or glycerin product with a combination of nicotine, flavorings, and/or other chemicals through an aerosol. The device usually includes a battery, a heating coil, an atomizer, a cartridge, which contains the e-liquid (also called “juice”), and a mouthpiece. The range of nicotine delivered to the user can vary according to the product type and brand, and is available in first-, second-, third-, and fourth-generation models, with some products not containing any nicotine at all.[87] The first-generation devices are disposable and resemble a cigarette, and the second-generation products are tank devices that can be recharged. Pod/pod mods are the third-generation products that allow for high levels of nicotine and are refillable, and the fourth-generation products are vape pens that are battery operated and can be refilled.[88] It has been suggested that using the ENDS products instead of smoking traditional cigarettes can eliminate the exposure to most of the toxins commonly seen in traditional cigarettes. However, no e-cigarette has been approved by the FDA as a cessation aid. A Cochrane review of 56 studies with over 12,000 currently smoking adults evaluated the use of quit rates with e-cigarette use compared to the quit rates of e-cigarettes without nicotine or traditional smoking cessation pharmacotherapy options including NRT, varenicline, and behavioral support. Overall there is moderate evidence supporting e-cigarettes as effective in achieving smoking cessation for 6 months or longer. There is some data to indicate e-cigarettes could be more effective than traditional smoking cessation treatments.[89] Adverse effects associated with e-cigarettes were limited and included coughing, throat and mouth irritation, and headache; all of which resolved with continuous exposure to the e-cigarettes. However, it was emphasized that more studies are needed since the overall evidence is low and concern over long-term health effects of e-cigarettes continues.[89] Thus, although ENDS may offer a possible benefit during the smoking cessation process, their use is controversial as the potential harms associated with their use are still being evaluated and studied.[41,71] E-cigarette use for smoking cessation has also been evaluated for use in pregnant individuals.[10] Although it has been well established that the exposure to toxins is much lower when using an e-cigarette compared to cigarette smoke, there are no long-term safety studies in humans to determine if e-cigarettes are safer than traditional cigarettes.[41,90]

In the fall of 2019, a severe lung illness related to use of e-cigarettes and vaping, referred to as “E-cigarette or Vaping use-Associated Lung Injury” (EVALI) was reported. By February 2020, over 2,800 patients were hospitalized, and 68 patients died. Most cases were linked to THC-containing products (82%), but some cases were linked to nicotine-only products. The EVALI outbreak was linked to an additive, vitamin E acetate, in predominately THC-containing products. A public awareness campaign was launched to educate the public on the risk associated with vaping THC or using THC-containing e-cigarettes. Additionally, vitamin E acetate was removed from products and law enforcement worked to remove illicit products from the market. Although these actions have decreased the number of EVALI cases reported, the CDC has stressed that there is insufficient evidence to rule out other chemicals as the cause of EVALI and further research is needed.[91]

The e-cigarettes have proven to be very appealing children, adolescents, and young adults due to the variety of devices, high concentration of nicotine, flavor-based products, and wide promotion of these products on social media.[41] Based on the data from the 2020 National Youth Tobacco Survey (NYTS), e-cigarettes use among middle school and high school students steadily increased from 2011 to an epidemic level peak in 2019, where 10.5% (1.24 million) of middle students and 27.5% (4.11 million) of high school students reported e-cigarette use.[92] Data from 2020 demonstrated a decrease in use among both age groups, where 4.7% of middle students (555,000) and 19.6% of high school students (3.02 million) reported current use of electronic cigarettes.[92] To improve regulation of these products, the Deeming Rule expanded the FDA’s regulatory authority to include manufacture, import, packaging, labeling, advertising, promotion, sale, and distribution of all tobacco products, including ENDS. This prohibited the sale of ENDS products to youth under 18 years of age, banning their sale in most vending machines (only allowed in adult-only facilities), or providing free samples. Manufacturers now have to receive marketing authorization from the FDA, and health warnings on ENDS and other tobacco products are now required.[93] Furthermore, vape shops that mix e-liquid must comply with the same legal requirements as tobacco manufacturers. In December 2019, the Federal Food, Drug, and Cosmetic Act was amended via the Tobacco 21 legislation to raise the federal minimum age of sale of tobacco products, including e-cigarettes, from the age of 18 to 21.[93] All 50 states and territories have now also restricted the sale of e-cigarettes to individuals 21 years of age and older.[94] The FDA additionally issued an enforcement policy focusing on the flavor-based e-cigarette products that appeal to adolescents.[93] Despite changes in regulations, these products are still very popular in the United States. The FDA continues to promote education campaigns, such as "The Real Cost" Youth E-Cigarette Prevention Campaign, which is aimed at youth who have experience with using ENDS or are considering trying these devices. Regardless, work continues in an effort to reduce the toxicity of the tobacco products, find ways to make products less appealing and less addictive, and improve the child-resistant packaging.[95]

The level of harm and/or risk associated with secondary passive exposure to ENDS aerosol is an ongoing debate, as passive exposure to the vapor emitted from the ENDS user could be hazardous based on a systematic review of 16 studies.[96] Data show e-cigarette vapor could expose bystanders to chemicals, including nicotine, glycine, formaldehyde, acetaldehyde, and propylene glycol, leading to an impact on indoor air quality. This risk, however, was noted to be lower than that associated with passive exposure from conventional cigarettes.[96] To limit second-hand exposure, many states have extended indoor smoking bans to include ENDS, although the laws for each state vary considerably.[94] The level of carcinogen and toxicant delivered to the user of the ENDS has been raised as a safety concern and due to the large variations in delivery devices and fluctuations in the amount of product a user will receive, it is difficult to study. While additional concerns have been raised regarding ENDS and toxic substances, the toxic levels of ENDS are estimated to be 1/4th to 1/95th the levels of the traditional cigarette.[97] Continued research is needed to evaluate the efficacy of e-cigarette use in regards to its role in helping with smoking cessation, youth exposure, and overall safety of this delivery system. Based on the current available evidence, USPSTF continues to recommend behavioral counseling and pharmacotherapy in nonpregnant adults and utilization of only behavioral counseling in pregnant individuals.[10]

Non-Nicotine Options

Bupropion (Zyban)

Pharmacologically, bupropion inhibits neuronal reuptake of norepinephrine and dopamine and potentiates their effects. Although its precise mechanism in smoking cessation is not well understood, bupropion's dopaminergic effects help reduce nicotine craving as dopamine neurotransmission is key to the brain's reward system.[71]

Bupropion SR is marked under the brand name Zyban and has been shown to be an effective treatment option for smoking cessation, although the brand product Wellbutrin contains the same pharmacological product.[76] A recent meta-analysis involving 155 trials showed that bupropion significantly increased the incidence of long-term cessation when used as a sole agent in 45 separate trials.[98]Other trials using bupropion as an add-on agent with NRT did not show bupropion had an additional benefit in improving cessation rates.[98] For smoking cessation, the manufacturer recommends a dosage of 150 mg once daily for 3 days and then twice daily (dosing should be at least 8 hours apart) for 7 to 12 weeks or longer, with or without NRT. Patients are instructed to initiate bupropion one week prior to the scheduled quit date and are encouraged to use counseling and support services along with the medication.[41] For maintenance therapy, consider bupropion SR 150 mg twice daily for up to 6 months.[71]

Contraindications to bupropion use include current or past seizure disorders, a history of monoamine oxidase inhibitor use over the last 14 days, and a history of anorexia nervosa or bulimia. Along with multiple other precautions listed in the product labeling, current alcohol use and use of medications that lower seizure threshold (eg, antidepressants and antipsychotics) are possible concerns when using this medication.[76] In 2009, the FDA required bupropion manufacturers to add new boxed warnings and to develop a medication guide highlighting the risk of serious neuropsychiatric symptoms in patients using this product. Possible symptoms include depressed mood, agitation, anxiety, hostility, changes in behavior, suicidal thoughts and behavior, and attempted suicide. However, in 2016 following a FDA-requested clinical trial review, the FDA announced the removal of the Black Box Warning and the Risk Evaluation and Mitigation Strategies (REMS) requirement for bupropion although continued to caution that the risk of mental health adverse effects are still possible, particularly in patients with a past history of mental health disorders or currently being treated for anxiety, depression, or schizophrenia.[41,99] The risk of adverse effects is higher with bupropion compared to placebo, including a higher rate of psychiatric adverse effects compared to placebo, leading to a higher number of discontinuation of treatment compared to placebo.[98]

Varenicline (Chantix)

8 Pharmacologically, varenicline is a partial agonist that binds selectively to α_4-β_2-nicotinic acetylcholine receptors (nAChRs) with a greater affinity than nicotine. When bound to the receptor, the medication blocks nicotine binding and also evokes a response, but to a lesser degree than nicotine.[73] Clinically, varenicline acts at sites in the nicotine-affected brain in two ways: by providing nicotine effects to ease withdrawal symptoms and by blocking the effects of nicotine from cigarettes if smoking is resumed. Additionally, varenicline has been found to have full agonist, although less potent, activity at α_7 and α_4-β_2 nAChRs and a full agonist at serotonin 3 receptor (5-HT_3).[100] A systematic review of 39 trials showed a two- to three-fold increased likelihood of long-term smoking cessation with varenicline compared with no NRT treatment (placebo).[101] Data from the trials included in this review also suggested that varenicline could have a role in relapse prevention and that it demonstrated better results compared to bupropion and NRT. These results were also seen in the largest randomized controlled trial for smoking cessation to date, the Evaluating Adverse Events in a Global Smoking Cessation Study (EAGLES) trial, which showed that varenicline is more efficacious than all other single NRTs, except for similar efficacy to the nicotine patch.[102]

The recommended dosage for varenicline is 0.5 mg daily for 3 days, increased to 0.5 mg twice daily for 3 days, and then increased to 1 mg twice daily for a standard 12-week treatment. It is suggested the quit date should be set for 1 week after initiating varenicline, but studies have shown allowing a flexible quit date is efficacious and safe. If abstinence has not been achieved after the 12-week treatment, then a second 12-week treatment may be prescribed.[103] Preloading varenicline for four weeks prior to the designated stop date has also demonstrated some higher response rates and can be considered as a treatment option.[104,105] Additionally, continuing varenicline as maintenance therapy for 6 months has been shown to decrease the risk of relapse.[41]

Common adverse effects associated with varenicline are nausea, vomiting, and insomnia. Over the years there have been concerns of neuropsychiatric adverse effects including suicidal thoughts, depression, and psychosis, leading to the black box warning. The previously mentioned EAGLES trial[102] also included a composite measure of neuropsychiatric symptoms as a primary safety endpoint and indicated there was no evidence of a significant increase in neuropsychiatric adverse effects which could be attributed to varenicline or bupropion. Specifically, in the individuals with psychiatric histories, moderate-to-severe neuropsychiatric symptoms were reported for varenicline (6.5%), bupropion (6.7%), nicotine patch (5.2%), and placebo (4.9%). In comparison, for patients without psychiatric histories, moderate-to-severe neuropsychiatric symptoms were reported as 1.3% to 2.5% of those enrolled in the trial. Overall, the risk differences reported for varenicline and bupropion versus placebo or the nicotine patch were nonsignificant. Following review of the trial results, the FDA announced the removal of the black box warning for varenicline and bupropion. In addition, a statement was included confirming bupropion, varenicline, and nicotine replacement patches are all more efficacious in smoking cessation compared to placebo regardless of mental illness history.[102] The most recent FDA Drug Safety communication indicates that although the risks of direct adverse effects from varenicline are lower than previously thought, the risk is still possible, especially in patients diagnosed with a mental illnesses, including schizophrenia, depression, or anxiety.[99] Cardiovascular safety concerns have also been raised regarding varenicline over the years and, to date, the results of various studies are still conflicting. In 2012, the FDA released a safety review update on the risk of cardiovascular adverse events indicating there is a higher risk of cardiovascular risks associated with varenicline.[106] However, results from the EAGLES extension trial, which was specifically designed to evaluate cardiovascular safety data, concluded there was no evidence of any cardiovascular adverse effects associated with these medications.[107]

Combination Therapy

Strong evidence exists for NRT combination therapy utilizing a short-acting form of NRT in combination with a nicotine patch based on a meta-analysis (RR 1.34; 95% CI: 1.18-1.48).[82] Additionally, a small systematic review and meta-analysis of 3 randomized controlled trials with 904 patients found that combining varenicline with NRT is more effective than varenicline alone. Individuals treated with both the nicotine patch and varenicline had similar adverse events to monotherapy except for skin reactions from the nicotine patch. Although the results for this study were positive for the combination, there were limited numbers of studies included in this analysis, so larger controlled clinical trials are needed.[108] Utilizing bupropion plus NRT has been shown to be more effective than bupropion monotherapy.[109] A meta-analysis evaluating the effectiveness of combining varenicline and bupropion in heavy smokers has demonstrated efficacy at 6 months but sustained cessation was not observed at 12 months. Increased reports of adverse effects including insomnia and anxiety were reported with the combination compared to varenicline monotherapy.[110]

Second-Line Medications

Second-line medications are therapeutic options for treating tobacco use, but have a more limited role than first-line medications because (a) the FDA has not approved them for smoking cessation and (b) there are more concerns about potential adverse medication effects than with first-line medications.[41] Although these second line medications have shown some efficacy for smoking cessation, they should only be considered for use on a case-by-case basis after first-line treatments have been used or considered.

Clonidine

Results from a meta-analysis of six trials showed that clonidine increased smoking cessation rates by 9%.[111] The main significant adverse effect reported with its use is hypotension, particularly postural hypotension; thus, blood pressure should be monitored.[111] Additional adverse effects include dry mouth, drowsiness, dizziness, and sedation. Overall, clonidine can be considered a second-line, off label, agent for smoking cessation.

Nortriptyline

Nortriptyline is also considered to be efficacious as a second-line agent for smoking cessation. When used for this indication, therapy is initiated 10 to 28 days before the quit date to allow for steady state to be reached at the target dose. Trials have initiated treatment at a dose of 25 mg/day, increasing gradually to a target dose of 75 to 100 mg/day.[111] Treatment duration used in smoking cessation trials have been approximately 12 weeks. A meta-analysis of 6 trials with 975 patients showed that nortriptyline as a sole agent is efficacious for smoking cessation when compared to placebo but is less efficacious when compared to varenicline.[98,112] Adding nortriptyline as an adjuvant to NRT did not prove to be an additional benefit in 4 trials which included over 1600 patients.[112] Most commonly reported adverse effects included sedation, dry mouth, blurred vision, urinary retention, light-headedness, and tremor.[113]

EVALUATION OF THERAPEUTIC OUTCOMES

Assisting a patient for tobacco cessation is a process that could take an extended period of time with extensive education and continual monitoring being vital to this process. The most effective treatment strategy for smoking cessation is a combination of behavioral and pharmacological treatment and frequent monitoring of both early on in the process is recommended. There are seven pharmacological treatment options and agent selection will be determined by a variety of factors. Patient counseling on selected pharmacotherapy options and common adverse effects is vital to ensure proper use and maximum efficacy. Frequent reassessment should occur to monitor overall treatment efficacy and to evaluate breakthrough cravings, withdrawal symptoms, and relapses. Dose adjustments should be made accordingly and individuals should be monitored closely and asked to immediately report any adverse effects to ensure proper adherence and prevent relapse.

INTRODUCTION—CAFFEINE

⑨ Caffeine is the most widely used psychoactive substance in the world, with approximately 90% of adults in the United States regularly consuming behaviorally active doses,[114] which result in psychoactive or stimulating responses including an increased sense of well-being, concentration, energy, alertness, and sociability. Caffeine is generally recognized as safe by the FDA for use in cola-type beverages as long as levels do not exceed 0.02% (200 parts per million),which is 30 to 40 mg of caffeine in a 12-oz (355 mL) serving.[115] A systematic review of data regarding potential adverse effects associated with caffeine found up to 400 mg caffeine per day in healthy adults was not associated with cardiovascular, behavioral, reproductive, or developmental adverse effects.[116] The FDA has cited that 400 mg per day, which is approximately four to five cups of coffee, is generally considered safe for adults.[114] However, in the United States, children consume an average 37.3 mg of caffeine per day.[117] Doses of 100 to 400 mg of caffeine have been reported to result in stimulant-related effects, such as jitteriness in children and adolescents. The American Academy of Pediatrics discourages children and adolescents consuming stimulants or caffeine due to the possible negative impact on sleep and blood pressure.[118] There is limited knowledge of caffeine effects on cognitive development and further study is necessary to determine the proper levels of safe consumption for this patient population.[115,117] Although, in general, caffeine consumption in reasonable amounts has been considered fairly safe, there are situations in which problems arise. Caffeinism has been associated with a daily caffeine intake of 1,000 to 1,500 mg. This term was coined to describe the clinical syndrome produced by acute or chronic unhealthy use of caffeine, which is usually characterized by central nervous system and peripheral manifestations, most notably, anxiety, psychomotor alterations, sleep disturbances, mood changes, and psychophysiological complaints.[119]

Pharmacologically, the risk of developing meaningful clinical manifestations from caffeine becomes high when intake exceeds 500 mg/day.[120] It could be assumed this level of caffeine might not be reached when traditionally drinking coffee. This helps explain why, up until recently, deaths from acute ingestions of caffeine were virtually nonexistent. However, pure caffeine powder and liquid formulations are available via the internet and just small doses could be toxic. One teaspoonful of highly concentrated powder is estimated to be equivalent to 28 cups of coffee (approximately 3,200 mg caffeine) and just one half cup of highly concentrated liquid is equivalent to approximately 20 cups of coffee (approximately 2,000 mg caffeine).[121] A 200 mg caffeine dose of pure caffeine powder is considered 1/16 teaspoon, where the caffeine liquid is 2.5 teaspoonfulls.[122] Due to the concerns of safety and reported deaths associated with concentrated caffeine products, the FDA has provided guidance documents to companies manufacturing, marketing, and distributing these products. Subsequent warning letters have been sent to all identified and who continue to sell illegal caffeine products.[122]

Caffeine in general has been proposed as a model of substance use despite the fact that its sale is largely unrestricted and that heavy consumption of caffeine-containing beverages is not considered to be problematic. The following information represents a broad overview of physical dependence, withdrawal, and tolerance. Interested readers are encourage to consult Meredith et al. and Sweeny et al. for further information.[123,124]

EPIDEMIOLOGY

Recently, data from the National Health and Nutrition Examination Survey (NHANES) 2007-2012 was evaluated regarding caffeine consumption through caffeinated beverages, foods, and energy drinks in adults 19 years of age and older. Approximately 90% of individuals in the United States consume caffeine daily, predominantly through caffeinated beverages (98%). The most common being coffee (64%), with tea and soft drinks being less popular (16% and 18%, respectively). Caffeine intake averaged 169 mg/day and mostly was consumed in the morning hours. Older adults, ages 75 to 79, consumed a greater amount of caffeine (153 mg/day) compared to younger adults ages 20 to 24 who averaged 107 mg/day. Caffeine intake varied with ethnicity, where non-Hispanic black individuals averaged the lowest caffeine consumption (80 mg/day) and non-Hispanic white individuals had the highest consumption averaging 194 mg/day.[114] Intake among children, adolescents, and young adults is prevalent from foods and beverages based on the 2011-2012 NHANES data. The average caffeine intake increased with age where 4- to 8-year-olds averaged 15 mg/day, 9- to 13-year-olds averaged 26 mg/day, and 14- to 19-year-olds averaged 61 mg/day.[125]

⑩ Energy drinks containing caffeine also include a variety of other products, such as taurine, vitamins, minerals, electrolytes, and sugar. These products are sold under brand names such as Red Bull, Monster Energy, Rockstar, and Bang Energy and are promoted to increase energy, enhance alertness, and physical performance. They continue to gain popularity among adolescents and emerging adults. Data from the 2003-2016 NHANES demonstrated an increase in consumption of energy drinks among a wide range of individuals, including adolescents (12-19 years old), young adults (20-39 years old), and middle-aged adults (40-59 years old). However, further analysis of the data did indicate that there could be a small decline in use patterns within the younger age groups, including adolescents and young adults, and an upward trend for middle-aged adults.[126] It is reported, aside from multivitamins, that these products are the most popular dietary supplement for young adults.[127] There are two types of products on the market based on volume. One product is similar to a soft drink, for example, Red Bull (8.4 oz [250 mL]) which contains 80 mg of caffeine, although other products can contain higher amounts of caffeine depending on the size of the container. The second product is a smaller volume product referred to as an "energy shot," which provides a range of 200 to 300 mg of caffeine in a 2- to 3-ounce product. Additionally, these products also commonly contain other products such as B vitamins, creatine, and CoQ10.[128]

Over the years, there have been many questions regarding the safety of these products and emergency room visits attributed to these energy drinks doubled from 2007 to 2011, with 58% of visits involving energy drinks alone and 42% including energy drinks with other substances including alcohol, marijuana, and/or stimulants.[129] Each year, the most common age group seen in the emergency room due to energy drink consumption included patients ages 18-25. However, energy drink related emergency visits in patients older than 40 year of age, has increased over 279%.[129] A recent study evaluated adverse event reports associated with energy drinks alone and in combination with other substances from 2008 to 2015. During this time period, a total of 13,179 reports were received on single product energy drinks and 1,084 reports on energy drinks combined with other substances.[130] A variety of health complications have been associated with their use in the adolescent population, including insomnia, arrhythmias, high blood pressure, agitation, anxiety and migraines.[131] Energy drink consumption has also been associated with a higher rate of unhealthy alcohol and substance use.[132]

PATHOPHYSIOLOGY

Caffeine is rapidly and completely absorbed from the GI tract, reaching a peak blood level within 30 to 60 minutes after oral ingestion. It easily crosses the blood–brain barrier, and levels achieved in the brain are proportional to the dose administered.[133] Caffeine is metabolized by cytochrome P450 1A2 (CYP1A2) and has a half-life of approximately 4 to 5 hours in healthy nonsmoking adults. Fast metabolizers of CYP1A2 include heavy caffeine users, children less than 12 years old, and individuals who smoke cigarettes. Individuals in later stages of pregnancy are slower metabolizers of caffeine, as are those with liver dysfunction.[119,133], Overdoses of caffeine are now more common due to the wide availability of energy drinks. Caffeine increases the heart rate and force of cardiac contractions, and also has a strong diuretic effect. Due to the stimulating properties of caffeine, nervousness, agitation, and insomnia may occur with more serious reactions including cardiac arrhythmias, hypotension, and seizures.[116,119] The key factor promoting caffeine use and dosage increases can be the substance's reinforcing effect on pleasure and reward centers of the brain. Caffeine's pharmacologic actions appear comparable (although less potent) to those of other stimulants, such as amphetamines and cocaine.[134]

CLINICAL PRESENTATION

The *DSM-5* has four caffeine-related diagnoses, including caffeine intoxication, caffeine withdrawal, other caffeine-induced disorders, which include both caffeine-induced sleep and anxiety disorders, and unspecified caffeine-related disorder. Each of these diagnoses could include symptoms which might be attributed to caffeine use, but do not fit in any other category. The *DSM-5* does not currently list a diagnosis of caffeine use disorder, but it has been identified as an area that needs further research to determine if it should become an official diagnosis.[5]

The diagnostic criteria for caffeine intoxication includes recent consumption of caffeine normally exceeding 250 mg and five or more symptoms during, or shortly after, consumption of caffeine. The symptoms of caffeine intoxication will usually decrease over 24 hours as the caffeine is eliminated from the body; however, consumption of very high doses of caffeine could be dangerous and require immediate medical attention.[5]

Caffeine withdrawal is a DSM-5 diagnosis, which occurs after the abrupt cessation of chronic caffeine use and can occur even with low doses of caffeine. The diagnosis of caffeine withdrawal requires three of the five listed symptoms, including headache (most common), marked fatigue or drowsiness, altered mood (depressed, irritable, and dysphoric), difficulty concentrating, or flu-like symptoms, including nausea, vomiting, and muscle pain/stiffness. The extent and severity of withdrawal can vary individually but normally will be more severe with higher chronic doses of caffeine (Table 86-7).[5]

TABLE 86-7

***DSM-5* Diagnostic Criteria for Caffeine Withdrawal**

Criteria
Prolonged daily use of caffeine Abrupt cessation or decrease use in caffeine leading to at least three of the following symptoms after 24 hours of cessation • Concentration problems • Mood changes: dysphoric mood, depressed mood, irritability • Dramatic fatigue or drowsiness • Headache • Flu-like symptoms • Nausea • Vomiting • Muscle pain/stiffness Symptoms negatively impact areas of functioning such as social or occupational aspects of life. The symptoms experienced cannot be explained by other concurrent medical conditions.

Data from References 5.

CLINICAL PRESENTATION: Caffeine Intoxication

General

- The individual may not be in acute distress.

Symptoms

- The individual may complain of nausea, vomiting, diarrhea, and psychomotor agitation, and can appear restless, nervous, and excited.

Signs

- The individual can present with facial flushing, diuresis, and muscle twitching.
- Tachycardia or cardiac arrhythmias can also occur.

Laboratory Tests

- Caffeine serum concentrations are rarely used clinically.

Effect on Sleep

Caffeine is commonly used to improve alertness and improve performance during times of sleep deprivation at doses of 75 to 150 mg. Sleep disruption can occur with caffeine consumptions ranging from 200 to 600 mg.[119] Caffeine's disruptive effects following a fixed dose of 400 mg provided 0, 3, and 6 hours prior to the usual bedtime has been associated with sleep disruption at all administration time periods.[135] However, any sleep disruption is likely to resolve 8 hours after caffeine consumption.[119]

Caffeine During Pregnancy

Over the years, there has been much discussion regarding the safety of caffeine intake during pregnancy and possible risks to the developing fetus. A systematic review of 380 studies published in 2017 evaluated data from 2001 through June 2015 and determined daily consumption of up to 300 mg of caffeine per day in a healthy pregnant individuals was not associated with any adverse health outcomes or developmental effects.[116] A narrative review which evaluated 42 original observational studies and 14 meta-analysis evaluating maternal consumption of caffeine during pregnancy reported increased negative outcomes during pregnancy including miscarriage, stillbirth, low birthweight/small gestational age. Additionally, increased risk of childhood leukemia as well as childhood overweight/obesity were identified in these studies.[136] Safe levels of caffeine consumption were recommended in this review; however, the author recommended based on this evidence, pregnant individuals should consider avoiding all caffeine consumption.[136] Currently, American College of Gynecology suggests limiting caffeine consumption to less than 200 mg per day and reports this level of caffeine intake has not been identified as a major contributing factor to miscarriage and preterm birth. Further information on the effect of caffeine intake on intrauterine growth was undetermined.[137] The March of Dimes also advises pregnant individuals to limit their caffeine intake to less than 200 mg/day.[138] Data will continued to be collected and evaluated to determine safe levels of caffeine consumption in pregnancy.

CLINICAL PRESENTATION: Caffeine Withdrawal

General

- The individual may not be in acute distress.

Symptoms

- Complaints of headache, nausea, vomiting, drowsiness, poor concentration, and depressed mood may be seen which are adversely affecting overall social/occupational functioning and/or leading to distress.

Laboratory Tests

- Caffeine serum concentrations are rarely used clinically.

TREATMENT

Desired Outcomes

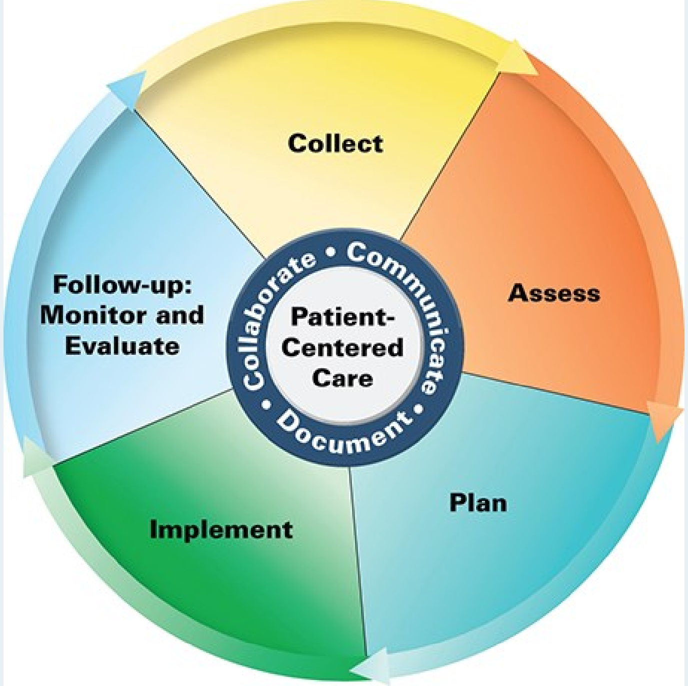
Many people drink coffee, tea, and other caffeinated beverages without problems. When adverse health effects occur (eg, insomnia, headaches, anxiety, and palpitations), it may be necessary to cut down on the amount of caffeine ingested or to eliminate it altogether to achieve elimination of these symptoms.

Nonpharmacologic Therapy

The primary treatment of caffeinism is reducing or discontinuing the use of the substance. For some it may be necessary to wean off the substance gradually because a rapid reduction in consumption can lead to adverse reactions, such as irritability, headaches, fatigue, flu-like symptoms, difficulty concentrating, and reduction in alertness.[123,124] The gradual reduction in caffeine intake over multiple days can reduce the risk of common withdrawal reactions.[139] For cases of extreme caffeine toxicity and withdrawal, necessary supportive measures should be instituted to prevent short- and or long-term sequelae.[118]

PATIENT CARE PROCESS

Patient Care Process for Alcohol Use Disorder



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient medical history (personal and family)
- Social history (eg, tobacco/alcohol use) and dietary habits
- Utilize CAGE questionnaire or Alcohol Use Disorders Identification Test (AUDIT) to assess for alcohol use disorder
- Current medications including prescription, over-the-counter (OTC), herbal products, dietary supplements
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Labs including serum creatinine (SCr), liver function tests (LFTs)

Assess

- Hemodynamic instability (eg, systolic BP <90 mm Hg, HR >110 bpm, O_2-sat <90% (0.90), RR >20) to assess for signs of acute alcohol withdrawal
- Utilize motivational interviewing to assess the individual's readiness to quit
- Ability/willingness to pay for pharmacotherapy options for Alcohol Use Disorder (AUD), and abstain from alcohol with disulfiram and avoid opiates with naltrexone
- Ability/willingness to obtain laboratory monitoring tests (eg, SCr [eg, naltrexone, acamprosate], LFTs [ie, disulfiram])
- Emotional status (eg, presence of anxiety, depression)

Plan*

- Pharmacotherapy regimen including specific AUD agent, dose, route, frequency, and duration (see Table 86-5)

- Monitoring parameters including efficacy (eg, decrease in craving, adherence) and safety (eg, adverse effects specific to selected agent, SCr, LFTs); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, medication-specific information, importance of adherence)
- Self-monitoring for adverse effects from pharmacotherapy treatment
- Referrals to other providers when appropriate (eg, behavioral health; highly recommended but not required for pharmacotherapy treatment)

Implement*

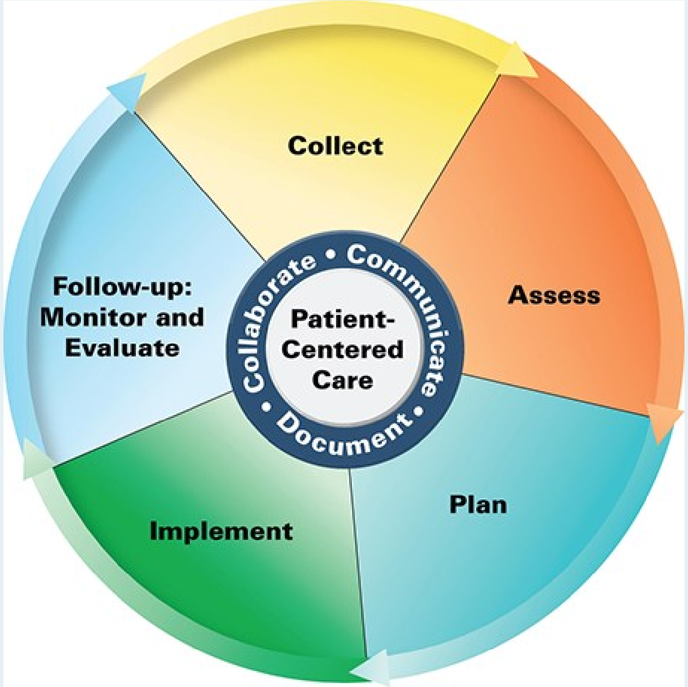
- Provide patient education regarding all elements of treatment plan
- Utilize motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, adherence assessment, SCr [eg, naltrexone, acamprosate], LFTs [eg, disulfiram])

Follow-Up: Monitor and Evaluate

- Presence of adverse effects (eg, medication specific)
- Individual adherence to treatment plan using multiple sources of information
- Reevaluate duration of therapy initially with frequent follow-up and then lengthen follow-up to every 1 to 2 months

**Collaborate with patient, caregivers, and other healthcare professionals.*

Patient Care Process for Smoking Cessation



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)

- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use) and dietary habits
- Smoking history (eg, current triggers, last cessation attempt, pharmacotherapy trials used in cessation, individual's level of interest for cessation at this time)
- Current medications including prescription, OTC use, herbal products, dietary supplements
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Labs including serum creatinine (SCr), liver function tests (LFTs)

Assess

- Hemodynamic stability (eg, systolic BP >90 mm Hg, HR <110 bpm, O_2-sat >90% (0.90), RR >20)
- Utilize motivational interviewing to assess readiness to quit
- Ability/willingness to pay for pharmacotherapy options and/or behavioral treatment for smoking cessation
- Ability/willingness to obtain laboratory monitoring tests (eg, LFTs [ie, bupropion], SCr [ie, varenicline])
- Emotional status (eg, presence of anxiety, depression)

Plan*

- Medication therapy regimen including specific nicotine replacement therapy (NRT), non-NRT, dose, route, frequency, and duration; (see Table 86-5 and Table 86-7)
- Monitoring parameters including efficacy (eg, decreases in craving, smoking) and safety (eg, adverse medication effects specific to selected agent); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, lifestyle modification, medication-specific information, medication administration technique; see Table 86-7)
- Self-monitoring for adverse medication effects from pharmacotherapy treatment
- Referrals to other providers when appropriate (eg, behavioral health; highly recommended but not required for pharmacotherapy treatment)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Set quit date if appropriate for this patient at this time (if appropriate)
- Schedule follow-up (eg, adherence assessment)

Follow-Up: Monitor and Evaluate*

- Quit date set
- Presence of adverse effects (eg, medication specific)

- Individual adherence to treatment plan using multiple sources of information
- Reevaluate duration of therapy initially with frequent follow-up and then lengthen follow up to every 1 to 2 months

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

EVALUATION OF THERAPEUTIC OUTCOMES

Identifying the treatment goals associated with the individual's current caffeine consumption and addressing these goals will be the primary focus in evaluating therapeutic outcomes. When an individual is working to reduce or discontinue caffeine, frequent reassessment should occur to monitor the individual for symptoms of caffeine withdrawal and educate on possible effects of withdrawal. If effects of withdrawal are experienced, appropriate adjustments should be made to improve reaching treatment goals.

CONCLUSION

Alcohol, nicotine, and caffeine are considered by most to be socially acceptable substances, yet they impose an enormous social and economic cost on our society. It is vital that all healthcare professionals continue to educate individuals on the healthcare risks of each of these substances to decrease the negative impact that can occur with their chronic use.

SELF-ASSESSMENT QUESTIONS

1. Based on the *DSM -5* criteria, an individual must meet ________ of the 11 criteria during a 12-month period to reach the diagnosis of alcohol use disorder (AUD).

   A. one

   B. two

   C. three

   D. four

2. The lethal dose of alcohol is associated with blood levels greater or equal to ____________.

   A. 100mg/dL (22 mmol/L)

   B. 200mg/dL (43 mmol/L)

   C. 300mg/dL (65 mmol/L)

   D. 400mg/dL (87 mmol/L)

3. Which of the following laboratory studies should be ordered in an individual suspected of alcohol ingestion?

   A. Blood alcohol concentration (BAC)

B. CBC (complete blood count)

C. CMP (complete metabolic panel)

D. All of the above

4. Which of the following assessment tools can be used when evaluating a patient in acute alcohol withdrawal?

    A. CAGE Questionnaire

    B. Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar)

    C. Alcohol Use Disorders Identification Test (AUDIT)

    D. Fast Alcohol Screening Test (FAST)

5. The preferred class of medications used in treatment of alcohol withdrawal is:

    A. barbiturates.

    B. antidepressants.

    C. benzodiazepines.

    D. antiseizure medications.

6. Which of the following treatment options will help prevent the development of Wernicke–Korsakoff syndrome?

    A. Thiamine

    B. Riboflavin

    C. Magnesium

    D. Biotin

7. There are four medications currently approved for pharmacological management of alcohol use disorder in the United States. Which of these approved agents is a GABAergic agonist that modulates alcohol cravings?

    A. Disulfiram

    B. Acamprosate

    C. Intramuscular naltrexone

    D. Oral naltrexone

8. Which of the following medications approved for the pharmacological management of alcohol use disorder would NOT be an appropriate choice for a patient with a recent history of a myocardial infarction?

    A. Disulfiram

    B. Oral naltrexone

    C. Intermuscular naltrexone

    D. Acamprosate

9. Which of the following NRTs would be appropriate for a 45-year-old individual who smokes 35 cigarettes per day? Upon further discussion, you discover they smoke their first cigarette about 10 minutes after waking up each morning. Past medical history includes hypertension, asthma, and seizure disorder. Medication allergies include angiotensin converting enzyme (ACE) Inhibitors and adhesive.

    A. Bupropion 150 mg PO daily for 3 days then increase to twice daily

    B. Nicotine gum 2 mg: chew and park gum as directed every 1 to 2 hours as needed

    C. Nicotine gum 4 mg: chew and park gum as directed every 1 to 2 hours as needed

    D. Nicotine patch 21 mg/day: apply 1 patch to skin daily; rotate application sites

10. Based on the USPSTF taskforce recommendations, which of the following statements is false?

    A. In nonpregnant adults, utilization of behavioral interventions along with FDA-approved pharmacotherapy agents for smoking cessation achieved a substantial benefit.

    B. For pregnant individuals, utilization of behavioral interventions demonstrated substantial benefit for both perinatal outcomes and improved smoking abstinence.

    C. For pregnant individuals, the only FDA-approved NRT agent suggested by the USPSTF was the Nicotrol inhaler.

    D. For both pregnant and nonpregnant adults, there evidence on use of ENDS is insufficient at this time so benefit vs. risk cannot be determined.

11. Which of the following agents is considered second-line therapy for smoking cessation treatment?

    A. Nicotine lozenge

    B. Bupropion

    C. Varenicline

    D. Nortriptyline

12. Which of the following statements is true regarding the Nicotine Patch?

    A. The patient must be told he should never smoke while wearing the patch

    B. If the patient has sleep disturbances, it is due to nicotine withdrawal and the patient should wear the patch through the night to decrease the sleep disturbances

    C. To improve adherence of the patch, after placing the patch on, hold the patch in place for 10 seconds.

    D. It is important to have a nicotine-free period, so it is important to take the patch off every night before going to bed

13. Per labeling, which of the following smoking cessation aids recommend smoking must stop before using this agent?

    A. Nicotine gum

    B. Nicotine lozenge

    C. Nicotrol inhaler

    D. Varenicline

14. Which statement is true regarding ENDS (electronic nicotine delivery systems)?

    A. Studies have now proved using ENDS is safer than traditional cigarettes and eliminates all exposure to toxins that are commonly seen in traditional cigarettes.

B. There is strong evidence that use of ENDS has now increased the odds of patients achieving full success with smoking cessation

C. Use of ENDS has dramatically increased among the middle school and high school age population and is now the most common tobacco product used in this age group.

D. Use of e-cigarettes is currently approved as a first-line therapy option based on smoking cessation treatment options.

15. A patient who is suffering from "Caffeinism" usually will have a daily intake of approximately _________mg of caffeine and commonly will demonstrate what typical common symptoms?

A. 500–600 mg: drowsiness/sedation/difficulties concentrating

B. 500,600 mg: anxiety/mood changes/psychomotor alterations

C. 1,000–1,500 mg: drowsiness/sedation/difficulties concentrating

D. 1,000–1,500 mg: anxiety/mood changes/psychomotor alterations

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B**. Two of the 11 *DSM -5* criteria must be met during a 12-month period to diagnose AUD. For more information, see "Epidemiology" for the Alcohol section in the chapter.

2. **D**. The lethal dose of alcohol occurs when blood alcohol levels are greater than 400 mg/dL (87 mmol/L). For more information, see the "Etiology" for Alcohol section in the chapter.

3. **D**. Laboratory studies that should be ordered for suspected alcohol ingestion would include a blood alcohol concentration, a complete blood count, and a complete metabolic panel. For more information, see the "Clinical Presentation: Alcohol Withdrawal" section in the chapter.

4. **B**. The Clinical Institute Withdrawal Assessment for Alcohol, revised (CIWA-Ar) is utilized to evaluate patients in acute alcohol withdrawal. For more information, see the "Clinical Presentation: Alcohol Withdrawal" section in the chapter.

5. **C**. Benzodiazepines are the class of medications that are the standard of care in alcohol detoxification. For more information, see the "Treatment of Alcohol Withdrawal Pharmacologic Therapy" section in the chapter.

6. **A**. Thiamine administration is important prior to the administration of glucose to prevent Wernicke–Korsakoff syndrome. See the "Treatment of Nutritional Deficits and Electrolyte Abnormalities" section in the chapter for more information.

7. **B**. Acamprosate is a GABAergic agonist that modulates alcohol cravings. For more information, see the "Pharmacologic Therapy for Alcohol" section in the chapter.

8. **A**. Disulfiram would not be an appropriate choice with a history of a myocardial infarction. If a patient consumes alcohol while taking disulfiram, the resulting disulfiram reaction can lead to myocardial infarction in severe cases. For more information, see the "Pharmacologic Therapy for Alcohol" section in the chapter.

9. **C**. Nicotine 4 mg based on TTFC (time to first cigarette), which is less than 30 minutes from arising. For more information, see the "Treatment" within the Nicotine section.

10. **C**. Nicotrol is Pregnancy Category D and the USPSTF has also highlighted there is inadequate evidence to suggest pharmacotherapy due to lack of studies to determine benefit vs risk at this time. See Table 86-7.

11. **D**. Nortriptyline is considered second-line therapy. All other options are considered first-line. For more information, see the "Second-Line Medications" section in the chapter.

12. **C**. Holding the patch on for 10 seconds when applying can improve adherence to the skin. See Table 86-7.

13. **C**. By label, it specifically states the patient should be counseled to stop smoking completely before using the Nicotrol inhaler. All other agents do state if patient continues to smoke, the patient will not be at risk. See Table 86-7.

14. **C**. The use of e-cigarettes in this age population has increased dramatically and so has the concern due to the exposure to nicotine. The FDA is working on this by working on education campaigns and also working to decrease the availability of these products to this demographic. For more information, see the "Electronic Nicotine Delivery Systems" section of the chapter.

15. **D**. This term has been associated with a daily intake of caffeine of 1,000 to 1,500 mg used to describe the clinical syndrome produced by acute or chronic overuse of caffeine which can be characterized by CNS and peripheral manifestations. For more information, see the "Introduction—Caffeine" section of the chapter.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 87: Schizophrenia

M. Lynn Crismon; Tawny L. Smith; Peter F. Buckley

KEY CONCEPTS

KEY CONCEPTS

①Although dysfunction in multiple neurotransmitters are involved in schizophrenia, the etiology is likely mediated by multiple subcellular processes that are influenced by different genetic polymorphisms.

②The clinical presentation of schizophrenia is characterized by positive symptoms, negative symptoms, and impairment in cognitive functioning.

③Comprehensive care for individuals with schizophrenia must occur in the context of a multidisciplinary mental healthcare environment that offers comprehensive psychosocial services in addition to psychotropic medication management.

④A thorough patient evaluation (eg, history, mental status examination, physical examination, psychiatric diagnostic interview, and laboratory analysis) should occur to establish a diagnosis of schizophrenia and to identify potential co-occurring disorders, including substance use disorders and general medical disorders.

⑤Given that it is challenging to differentiate among antipsychotics based on efficacy, adverse medication reaction profiles become important in choosing an antipsychotic for an individual patient.

⑥Pharmacotherapy guidelines should emphasize antipsychotic monotherapies that optimize benefit-to-risk ratios before progressing to medications with greater adverse reaction risks. Combination regimens should only be used in the most treatment-resistant patients.

⑦Adequate time on a given medication at a therapeutic dose is the most important variable in predicting medication response.

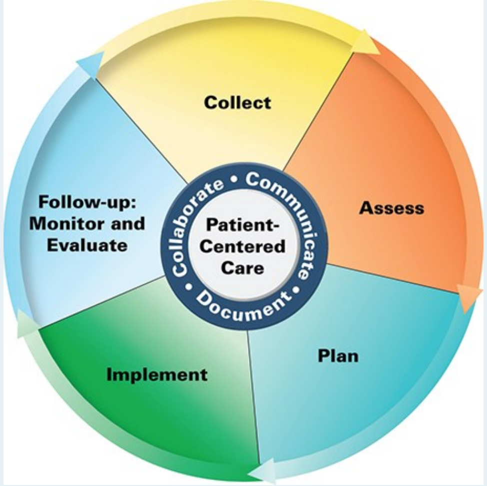
⑧Long-term maintenance antipsychotic treatment is necessary for most patients with schizophrenia in order to prevent relapse.

⑨Thorough patient and family psychoeducation should be implemented, utilizing motivational interviewing methods that focus on patient-driven outcomes in an effort to allow patients to achieve life goals.

⑩Pharmacotherapy decisions should be guided by systematic monitoring of patient symptoms, preferably with the use of brief symptom rating scales and systematic assessment of potential adverse effects.

PATIENT CARE PROCESS

Patient Care Process for Schizophrenia



Collect
Assess
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •
Plan
Implement

Collect

- Patient characteristics (eg, age, race, sex, gender identity, pregnancy status)
- Patient history (past mental and medical, medication adherence, family, social—diet, alcohol and substance use, tobacco use)
- Mental status exam
- Medications (current and past)
- Objective data

- Brief Positive and Negative Symptom Scales (see Table 87-11)
- Blood pressure (BP), heart rate (HR), height, weight, and body mass index (BMI) (see Table 87-12)
- Labs: Hemoglobin A1c (HgA1c), lipids, other tests if indicated (see Table 87-12)

Assess

- Patient's concerns and attitudes toward treatment, medication adherence (see Table 87-5)
- Symptom severity and the extent that treatment goals have been met
- Do any co-occurring disorders (mental, substance use disorder, medical) need to be addressed?
- Are patient's psychosocial needs being met? (see Table 87-2)
- Adverse medication reactions (see Tables 87-7 and 87-12)
- Potential for medication interactions (see Tables 87-9 and 87-10)
- Appropriateness and effectiveness of current psychotropic regimen

Plan*

- Actively engage patient in care plan
- Medication therapy regimen (egspecify the continuation and discontinuation of existing therapies) (see Fig. 87-1 and Tables 87-3, 87-4, and 87-6)
- Monitoring parameters including efficacy and time frame (see Tables 87-11 and 87-12)
- Patient education (eg, medication, life style management)
- Referrals to other providers as appropriate (eg, physician, psychologist, social worker)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate*

- Determine symptom attainment (see Table 87-11)
- Presence of adverse effects (see Table 87-12)
- Presence of medication interactions (see Tables 87-9 and 87-10)
- Need for psychosocial interventions
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the approximately 9-minute video on YouTube, "Four Patients with Schizophrenia."

For each of the patients, list the symptoms that are associated with schizophrenia. Use Table 87-11 as a reference, and for each patient list those symptoms that are present on the Brief Positive and Negative Symptom Scales. The intent of this learning activity is to help you identify symptoms associated with schizophrenia and identify symptoms that can be used to monitor response to pharmacotherapy.

INTRODUCTION

Schizophrenia is one of the most complex and challenging psychiatric disorders as it represents a heterogeneous syndrome of disorganized and bizarre thoughts, delusions, hallucinations, inappropriate affect, and impaired psychosocial functioning. From the time that Kraepelin first described dementia praecox in 1896 until publication of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) in 2013, the description of this illness has continuously evolved.[1] Scientific advances that increase our knowledge of central nervous system (CNS) physiology, pathophysiology, and genetics will likely improve our understanding of schizophrenia in the future.

EPIDEMIOLOGY

The lifetime prevalence of schizophrenia ranges from 0.28% to 0.6%[2] with the worldwide prevalence being similar among most cultures. Schizophrenia most commonly has its onset in late adolescence or early adulthood and rarely occurs before adolescence or after the age of 40 years. Although the prevalence of schizophrenia is equal between the sexes, the onset of illness tends to be earlier in males as they typically have their first episode during their early 20s, whereas with females it is usually during their late 20s.[1]

ETIOLOGY

Although the etiology of schizophrenia is unknown, research has demonstrated various abnormalities in brain structure and function.[3] However, these changes are not consistent among all individuals with schizophrenia. The cause of schizophrenia is likely multifactorial, that is, multiple pathophysiologic abnormalities can play a role in producing the similar but varying clinical phenotypes we refer to as schizophrenia.

A neurodevelopmental model, formed from the study of brains from individuals diagnosed with schizophrenia, has been evoked as one possible explanation for its etiology.[3,4] Although many different avenues of research have been undertaken, most find that biological and functional abnormalities in cell shape, position, symmetry, and connectivity have been associated with development of abnormal brain circuits that lead to the symptoms seen in schizophrenia.[4] The changes seen as part of this research are consistent with a cell migration abnormality during the second trimester of pregnancy, and some studies associate upper respiratory infections during the second trimester of pregnancy with a higher incidence of schizophrenia.[4] Other studies associate low birth weight (LBW; less than 2.5 kg [5.5 lb]), obstetric complications, or neonatal hypoxia with schizophrenia.[4] Theories of maternal stress have been developed which may be related to aberrations in circulating glucocorticoids in utero as a risk factor for schizophrenia.[4] Although imaging studies show decreased cortical thickness and increased ventricular size in the brains of many patients with schizophrenia, this occurs in the absence of widespread changes in the glial cells (or gliosis).[4] One hypothesis for these changes is that obstetric complications and hypoxia, in combination with a genetic predisposition, could activate a glutamatergic cascade resulting in increased neuronal pruning. Genes controlling *N*-methyl-D-aspartate (NMDA) receptor activity are hypothesized to be part of this process, as dendrite pruning, which is part of normal neurodevelopmental process, is higher in individuals with schizophrenia. As synaptic pruning predominantly involves glutamatergic dendrites, hypoxia or other prenatal insults can result in fewer basal neurons overall, and glutamatergic activation can exaggerate the pruning process.[3,4] Furthermore, a relationship has been documented between autoimmune encephalitis and psychosis, which is based upon glutamate receptor autoantibodies. This is important as studies have shown an increased susceptibility to immune/autoimmune disorders in schizophrenia, as well as abnormalities of autoantibodies and cytokine functioning.[5] Although this etiology is felt to be uncommon, it serves as a model for the heuristic immune hypothesis of schizophrenia, which also emphasizes integration of mental and physical well-being.[5] A plethora of diverse findings point to immune dysfunction in schizophrenia.

Numerous studies have shown neuropsychological abnormalities, impairment in reaching normal motor milestones and abnormal movements, in young children who later develop schizophrenia.[4] These abnormalities in brain function occur long before the onset of psychotic symptomatology and provide empirical evidence for schizophrenia being a neurodevelopmental disorder.[2] Furthermore, brain imaging studies show deteriorative brain changes in patients with frequent relapses,[4,6] with these changes being most pronounced among adolescents with early onset schizophrenia.[4,7] Therefore, continued pathophysiological changes, secondary to the original neurodevelopmental insult, may lead to the first psychotic episode, and brain morphology resembling neurodegeneration.[3,4,7]

Although the risk of developing schizophrenia is estimated as 0.28% to 0.6% worldwide, the risk is approximately 3% if a second-degree relative has the illness and 10% if there is a first-degree relative.[4] If both parents have schizophrenia, the risk of schizophrenia, to the offspring, increases to approximately 40%. Dizygotic twins report a 12% to 14% risk if one twin has the illness, with this increasing to 48% for monozygotic twins.[4] Furthermore, in siblings the onset of illness tends to occur at the same age in each, and adoption studies indicate that environmental changes during the child's developmental stages do not alter their genetic risk, both of which give less credence to the possibility of an environmental precipitant.

① Numerous approaches have been utilized to study the genetics of neurodevelopment and schizophrenia risk, but one single genetic risk factor has not been found.[7] Genome-wide association studies (GWAS) have identified over 120 genetic small-effect loci that account for a small percent of the risk.[3,7] Of major interest is the finding that polymorphisms of the complement component 4 (*C4*) genes on chromosome 6 may be implicated in the abnormal dendritic pruning seen in individuals with schizophrenia.[8] Additionally, schizophrenia risk has been increasingly linked to about a dozen recurrent copy number variants (CNV) that have high penetrance; however, cumulatively they likely account for no more than 1% to 2% of all cases.[3,7] Genetic risk has also been attributed to the synaptic protein neurexin 1 (NRXN1) and neuregulin 1 (NRG1) which, in particular, may increase the risk of developing the first psychotic episode for those who are already at high risk.[3] MicroRNAs (mRNA), which are small noncoding RNAs critical to neurodevelopment and regulation of adult neuronal processes, have also been linked to schizophrenia risk and are being actively explored.[3]

There is an overlap—both clinically and biologically—between schizophrenia and mood disorders with single nucleotide polymorphisms (SNPs) from chromosomes 3, 10, and 12 being common across schizophrenia, bipolar disorder, and major depression. Two of these SNPs were at loci related to the pathophysiology of calcium-channels.[3,7] Some of the CMVs identified for schizophrenia risk have also been associated with autism spectrum disorder, intellectual disability, and attention-deficit hyperactivity disorder.[7] Thus, several genetic and biological studies now suggest a greater shared genetic—and neurobiological—basis across psychiatric disorders so that the idea of schizophrenia being a distinct "condition" is increasingly being challenged.

PATHOPHYSIOLOGY

Studies have found consistent decreases in gray matter in multiple brain areas, including the frontal lobes, cingulate gyri, and medial temporal regions among others. A longitudinal study of high-risk youth showed a substantially greater decrease in gray matter in high-risk youth who progressed to psychosis than in high-risk youth who did not progress to psychosis or in normal controls.[9] Additionally, increases in ventricular size, as well as decreased white matter in the corpus callosum, have been observed.[9] Changes in hippocampal volume may correspond with impairment in neuropsychological testing.[4,6] It is felt then, that rather than a decrease in the number of neurons in affected brain areas, a decrease in axonal and dendritic communications between cells can result in a loss of connectivity impacting neuronal adaptivity and CNS homeostasis,[4,6] which are likely consistent with the evidence for abnormal neuronal pruning.[2] Intense research efforts have been made to explore and link brain imaging and other biomarkers to disease expression and progression, in an effort to arrive at clinically relevant biomarkers that could aid treatment of schizophrenia—just as has occurred in cancer and other medical conditions.

① Historically, schizophrenia has been attributed to dopamine (DA) receptor defects, but increasingly subcortical dopaminergic dysregulation, including increased DA synthesis and release have been observed.[10] While presynaptic changes in dopaminergic neurons occur and are consistent with the neurodevelopmental model that has been proposed,[3,6] numerous positron emission tomography (PET) studies have shown brain abnormalities including increased glucose metabolism in the caudate nucleus and decreased blood flow and glucose metabolism in the frontal lobe and left temporal lobe.[4] These findings may indicate dopaminergic hyperactivity in the head of the caudate nucleus and dopaminergic hypofunction in the frontotemporal regions, which may be confirmed by alterations in dopamine-2 (D_2) receptors densities.[4,6] However, increases in presynaptic DA synthesis and release into the striatum may only translate into a small increase in $D_{2/3}$ receptor availability.[11]

Additionally, PET studies assessing dopamine-1 (D_1) receptor function suggest that subpopulations of patients with schizophrenia may have decreased densities of D_1 receptors in the caudate nucleus and the prefrontal cortex, in addition to the D_2 receptors. Clinically this may lead to hypofrontality within the prefrontal cortex, which can be associated with a lack of volition and cognitive dysfunction, core features of schizophrenia. It is unknown whether these changes represent a primary event or secondary processes related to other pathophysiologic abnormalities in schizophrenia. Because of the heterogeneity in the clinical presentation of schizophrenia, the DA hypothesis may be more applicable to individuals who respond to antipsychotic treatment, with multiple different etiologies possibly being responsible for causing schizophrenia.[4,6] While attempts have been made to develop relationships between these abnormal findings and behavioral symptoms present in patients with schizophrenia, the positive symptoms of schizophrenia are possibly more closely associated with DA-receptor hyperactivity in the mesocaudate, whereas negative symptoms and cognitive impairment are most closely related to DA-receptor hypofunction in the prefrontal cortex. As the presynaptic D_1 receptors in the prefrontal cortex are thought to be involved in modulating glutamatergic activity, this hypofunctionality can impact working memory in individuals with schizophrenia.[4,6]

One can examine different neurotransmitter alterations in the context of different proposed phases of schizophrenia.[12] The Predrome phase typically occurs before an individual is diagnosed with schizophrenia.

This phase can last weeks to years where clinically high-risk individuals are thought to exhibit glutamategic synaptic dysfunction that results in a glutamate signaling defect, leading to some affective and/or psychotic symptoms. Partial compensation by gamma-aminobutyric acid (GABA) downregulation and synaptic proliferation are associated with the Prodromal Phase. This deficit in GABA is felt to result in less inhibition of excitatory circuits, producing dopaminergic dysfunction, the onset of psychosis, and the Syndrome Phase, with the degree of dopamine dysfunction associated with more severe disease.[6] During the Syndrome Phase, most individuals are officially diagnosed with schizophrenia. In the last phase, the Chronic Phase, years of chronic schizophrenia symptoms and treatments are thought to be associated with the loss of gray matter compounding the synaptic deficits.[12]

As the glutamatergic system is one of the most widespread excitatory neurotransmitter systems in the brain, hypo- or hyperactive alterations in function can result in toxic neuronal reactions.[12] Dopaminergic innervation from glutamate in the ventral striatum decreases the limbic system's inhibitory activity (perhaps through GABA interneurons) and thus increases arousal. The corticostriatal glutamate pathways have the opposite effect, whereas inhibiting dopaminergic function from the ventral striatum allows increased inhibitory activity in the limbic system. Due to the interaction between glutamatergic and dopaminergic tracts, as well as through GABA interneurons, glutamatergic deficiency produces symptoms similar to those of dopaminergic hyperactivity and possibly those seen in schizophrenia. Therefore, alterations in the interactions between dopamine and glutamate due to NMDA hypofunction have been associated with the latent clinical expression of psychotic symptoms in late adolescence or early adulthood.

Schizophrenia is a complex disorder, and multiple etiologies likely exist. Based on current knowledge, it is naïve to think that any one proposed etiology or one dysfunction in neurotransmission can adequately explain the genesis of this complex disease. Moreover, ongoing research into distinct biomarkers for schizophrenia, as well as the promise of stem cell research to disentangle the pathobiology of this enigmatic disorder, will also help identify phenotypes and help to determine the boundaries between psychosis and mood disorders.[3,7,11,13]

CLINICAL PRESENTATION

The clinical presentation of functional psychosis seen with schizophrenia is highly variable. Despite numerous attempts to portray a stereotype in movies and on television, the stereotypic person with schizophrenia essentially does not exist, and schizophrenia is not a "split personality." It is a chronic disorder of thought and affect with the individual having a significant disturbance in interpersonal relationships and ability to function in society.

② The first psychotic episode can be sudden in onset with few premorbid symptoms, or more commonly is preceded by withdrawn, suspicious, peculiar behavior, termed schizoid. During acute psychotic episodes, the patient loses touch with reality, and in a sense, the brain creates a false reality to replace it. Acute psychotic symptoms can include hallucinations (especially hearing voices), delusions (fixed false beliefs), and ideas of influence (beliefs that one's actions are controlled by external influences). Thought processes are disconnected (loose associations), the patient may not be able to carry on logical conversation (alogia), and can have simultaneous contradictory thoughts (ambivalence). The patient's affect can be flat (no emotional expression), or it can be inappropriate and labile. The patient is often withdrawn and inwardly directed (autism). Uncooperativeness, hostility, and verbal or physical aggression can be seen because of the patient's misperception of reality. Self-care skills are impaired, and patients may be dirty and unkempt with generally poor hygiene during acute episodes. Sleep and appetite are often disturbed. When the acute psychotic episode remits, the patient typically has residual features, which is an important point in differentiating schizophrenia from other psychotic disorders. Although residual symptoms and their severity vary, patients can have difficulty with anxiety management, suspiciousness, and lack of volition, motivation, insight, and judgment. They often have difficulty living independently, and because of poor anxiety management and suspiciousness, they are frequently withdrawn socially, and have difficulty forming close relationships with others. Impaired volition and motivation contribute to poor self-care skills and make it difficult for the patient with schizophrenia to maintain employment.

Patients with schizophrenia frequently experience a lack of historicity, or difficulty in learning from their experiences, resulting in them repeatedly making the same mistakes in social conduct and situations requiring judgment. They have difficulty understanding the importance of treatment, including medications, in maintaining their ability to function. Therefore, they tend to discontinue treatments, increasing the risk of relapse and rehospitalization.

The co-occurrence of substance use disorder (SUD) (predominantly alcohol or polysubstance—alcohol, cannabis, and cocaine) in patients with schizophrenia is very common and is another frequent reason for relapse and hospitalization.[1] This effect can be caused by direct toxic effects of these substances on the brain,[14] but is also caused by the medication nonadherence that is associated with substance use. Some substances—most notably heavy cannabis use during adolescence—have been associated with a higher prevalence of schizophrenia, as cannabis use raises the risk of schizophrenia four- to sixfold.[15]

Although the course of schizophrenia is variable, the long-term prognosis for many patients is poor. It is marked by intermittent acute psychotic episodes and impaired psychosocial functioning between acute episodes, with most of the deterioration in psychosocial functioning occurring within 5 years after the first psychotic episode.[16] By late life, the patient can appear "burned out," that is, they cease to have acute psychotic episodes, but residual symptoms persist (the chronic phase). In a subpopulation of patients, probably 5% to 15%, psychotic symptoms are nearly continuous, and response to antipsychotics is poor.[16]

Schizophrenia is a chronic disorder, and the patient's history must be carefully assessed for dysfunction that has persisted for longer than 6 months. After their first episode, patients with schizophrenia rarely have a level of adaptive functioning as high as before the onset of the disorder. *The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) should be consulted for the complete criteria for a diagnosis of schizophrenia.[1] The *DSM-5* also asks the clinician to specify the episode severity for schizophrenia after having the diagnosis for at least 1 year and whether the patient is presenting with catatonia.[1]

The *DSM-5* classifies the symptoms of schizophrenia into two categories: positive and negative; however, greater emphasis is now being placed on a third symptom category, cognitive dysfunction.[1,16] The areas of cognition found to be abnormal in schizophrenia include attention, working memory, and executive function. Positive symptoms have traditionally attracted the most attention and are the ones most improved by antipsychotics. However, negative symptoms and impairment in cognition are more closely associated with poor psychosocial function.

CLINICAL PRESENTATION: Schizophrenia and Symptoms Clusters

Positive Symptoms

- Suspiciousness
- Unusual thought content (delusions)
- Hallucinations
- Conceptual disorganization

Negative Symptoms

- Affective flattening
- Alogia
- Anhedonia
- Avolition

Cognitive Symptoms

- Impaired attention
- Impaired working memory
- Impaired executive function

Along with these characteristic features of schizophrenia, many patients also have comorbid psychiatric and general medical disorders.[2,16] These include depression, anxiety disorders, SUD, and general medical disorders such as respiratory disorders, cardiovascular disorders, and metabolic disturbances. These comorbidities substantially complicate the clinical presentation and course of schizophrenia.

Symptom complexes are correlated with prognosis, cognitive functioning, structural abnormalities in the brain, and response to antipsychotic medications. Negative symptoms and cognitive impairment are more closely associated with prefrontal lobe dysfunction and positive symptoms with temporolimbic abnormalities. As many patients demonstrate both positive and negative symptoms, those with negative symptoms frequently have more antecedent cognitive dysfunction, poor premorbid adjustment, low level of educational achievement, and a poorer overall prognosis.[1,16]

TREATMENT

Desired Outcome

③ Pharmacotherapy is a mainstay of treatment in schizophrenia, as it is impossible to effectively implement psychosocial rehabilitation programs without antipsychotic treatment in most patients.[14] The most current treatment guidelines for schizophrenia espouse 24 recommendations, three of which relate to overall assessment and treatment planning, 11 of which cover medication treatments, and the remaining 10 focus on psychosocial approaches to care (Table 87-1). A pharmacotherapeutic treatment plan should be developed that delineates medication-related aspects of therapy. Most deterioration in psychosocial functioning occurs during the first 5 years after the initial psychotic episode, and treatment should be particularly assertive during this period.[16] The individualized treatment plan created for each patient should have explicit end points defined, including realistic goals for the target symptoms most likely to respond, and the relative time course for response.[17] Other desired outcomes include avoiding unwanted adverse medication reactions, integrating the patient back into the community, increasing adaptive functioning to the extent possible, and preventing relapse.

TABLE 87-1

Guidelines for the Care of Patients with Schizophrenia

Patients have a comprehensive initial assessment
Initial education includes a quantitative measure of symptoms—functioning
Treatment planning includes evidence based pharmacologic and nonpharmacologic treatments
Patients receive antipsychotic medications for treatment, evaluating both efficacy and safety
Patients whose illness has improved with medication receive continued antipsychotic treatment
Patients with treatment resistant schizophrenia receive clozapine
Patients with persistent suicidality/risk of suicidality despite other treatments, receive clozapine
*Patients with aggression that persists despite other treatments receive clozapine
*Patients with preference and/or history of inadequate medication noncompliance receive long-acting injectable antipsychotic medication
Patients with antipsychotic-induced dystonia receive an anticholinergic medicine
*Patients with antipsychotic-induced parkinson symptoms have their medication dosage reduced or switched to another antipsychotic or receive an anticholinergic medication
*Patients with antipsychotic induced akathisia have their medication dosage reduced, switch to another antipsychotic, or receive either a benzodiazepine or beta blocker
Patients with at least moderate tardive dyskinesia that is antipsychotic induced receive a vesicular monoamine transporter 2 (VMAT2) reversible inhibitor
Patients with first episode psychosis are treated in a comprehensive program
Patients receive cognitive behavioral therapy
Patients receive psychoeducation
Patients receive supported employment opportunities
Patients with social complications contributing to recurrent relapses receive assertive community treatment
*Patients with family contact receive family supportive activities
*Patients receive recovery-based activities
*Patients receive cognitive remediation
*Patients with focus on social performances receive social skills training
*Patients receive supportive psychotherapy

** Recommended or suggested by the American Psychiatric Association (APA). Data from References 18 and 20-22.*

Nonpharmacologic Therapy

Psychosocial rehabilitation programs focused on improving patients' adaptive functioning are the mainstay of non-medication treatment for schizophrenia. These programs include case management, psychoeducation, targeted cognitive therapy, basic living skills, social skills training, basic education, work programs, supported housing, and financial support. In particular, programs aimed at supportive employment and housing are effective and considered "best practices." Those that involve families in the care and life of the patient have been shown to decrease rehospitalization and improve functioning in the community. For particularly low-functioning patients, assertive intervention programs, referred to as *active community treatment* (ACT), are effective in improving patients' functional outcomes. These ACT teams are available on a 24-hour basis and work in the patient's home and/or place of employment to provide comprehensive treatment, including medication, crisis intervention, daily living skills, and supported employment and housing.[18] Pharmacotherapy cannot be successful without proper attention to these other aspects of care, as people with schizophrenia need comprehensive care, with coordination of services across psychiatric, SUD, medical, social, and rehabilitative services. In the United States, care coordination is often insufficient, putting patients at risk to "fall through the cracks." Some countries have implemented more robust primary and secondary preventative approaches, highlighting early identification, ease of access to care, and staging of disease management.[19] The National Institute of Mental Health (NIMH) Recovery After Initial Schizophrenia Episode (RAISE) study found that four core interventions ("personalized medication management, family psychoeducation, resilience-focused individual therapy, and supported employment and education") significantly improved the quality of life over a 24-month period for individuals with early schizophrenia as compared to usual community care.[20]

The patient-centered approach to the recovery-based system of care is growing, where the person's lifetime aspirations and goals become the center of care, rather than symptom reduction being the primary focus. This recovery-based approach recognizes the strengths and resilience of people with schizophrenia, and acknowledges how people with schizophrenia can be a support to others who are living with the illness.[20] It is important to frame clinical decision making in the context of a mutual process involving patient and clinician. Psychosocial/cognitive behavioral strategies can help some patients, and emerging computer-based therapies and social media–related approaches may be helpful. Cognitive remediation—which uses computer-based cognitive retraining techniques—has been shown to be of benefit.[21] Social media and mobile technology strategies may be harnessed to improve communications, medication adherence, and potentially detect early warning signs of impending relapse in patients with schizophrenia.

Pharmacologic Therapy

④ The importance of an initial accurate diagnostic assessment cannot be overemphasized. A thorough mental status examination (MSE), psychiatric diagnostic interview, physical and neurologic examination, complete family and social history, and laboratory workup must be performed to confirm the diagnosis and exclude general medical or substance-induced causes of psychosis. Laboratory tests, biologic markers, and commonly available brain imaging techniques do not assist in the diagnosis of schizophrenia or selection of medication. A pretreatment patient workup not only is important in excluding other pathology but also serves as a baseline for monitoring potential adverse medication reactions, and should include vital signs, complete blood count, electrolytes, hepatic function, renal function, electrocardiogram (ECG), fasting serum glucose, hemoglobin A1c, serum lipids, thyroid function, and urine drug screen.

⑤ Both first-generation antipsychotics (FGAs, also known as traditional) and second-generation antipsychotics (SGAs, also known as atypical) are used in the treatment of schizophrenia,[14,23] with no absolute criterion distinguishing between the two. As compared with FGAs, SGAs appear to have the ability to produce antipsychotic response with fewer occurring extrapyramidal symptoms (EPS). Other attributes that have been ascribed to some SGAs include enhanced efficacy (particularly for negative symptoms and cognition), near absence of propensity to cause tardive dyskinesia, and lack of effect on serum prolactin.[24] To date, only clozapine truly fulfills all of these criteria, with other SGAs having some of these attributes.[24] Therefore, the major factor used in practice when distinguishing among antipsychotics is adverse effects.[22-24] While the SGAs have a lower risk of neurologic adverse reactions, particularly effects on movement, this is offset by increased risk of metabolic syndrome with some SGAs, including weight gain, hyperlipidemias, and diabetes mellitus. Adverse medication reaction profiles differ among antipsychotics, and this information should be used in combination with individual patient characteristics when choosing a medication for an individual patient.

Results from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study, primarily in patients with chronic schizophrenia, indicate that olanzapine, compared with quetiapine, risperidone, ziprasidone, and the FGA perphenazine, had modest but not statistically significant superiority in maintenance therapy with treatment persistence as the primary clinical outcome.[17] However, increased metabolic effects occurred with olanzapine, and additional studies of patients early on in their illness highlight the high rate of cardiometabolic disturbances with olanzapine and the need to tailor treatment.[25]

Previous patient or family history of response to an antipsychotic is helpful in the selection of an agent. Acquisition cost varies significantly among different antipsychotics and dosage forms, and should be considered in context of any potential advantages of an agent. Table 87-2 lists antipsychotics and their usual dosage ranges.

TABLE 87-2

Available Antipsychotics and Dosage Ranges

Generic Name	Trade Name	Starting Dose (mg/day)	Usual Dosage Range (mg/day)	Comments
First-Generation Antipsychotics				
Chlorpromazine	Thorazine	50-150	300-1,000	Most weight gain among FGAs
Fluphenazine	Prolixin	5	5-20	
Haloperidol	Haldol	2-5	2-20	Higher dropout rate in first episode
Loxapine	Loxitane	20	50-150	
Loxapine inhaled	Adasuve	10	10	Maximum 10 mg per 24 hours Approved REMS program only
Perphenazine	Trilafon	4-24	16-64	
Thioridazine	Mellaril	50-150	100-800	Significant QTc prolongation
Thiothixene	Navane	4-10	4-50	
Trifluoperazine	Stelazine	2-5	5-40	
Second-Generation Antipsychotics				
Aripiprazole	Abilify	5-15	15-30	
Asenapine	Saphris	5	10-20	Sublingual only, no food or drink for 10 minutes after administration
Brexpiprazole	Rexulti	1	2-4	
Cariprazine	Vraylar	1.5	1.5-6	Due to long half-life, steady state is not reached for several weeks
Clozapine	Clozaril	25	100-800	REMS program; Check plasma level before exceeding 600 mg
Iloperidone	Fanapt	1-2	6-24	Care with dosing in CYP2D6 slow metabolizers
Lumateperone	Caplyta	42	42	Bioavailability increased by 9% when administered with high fat meal
Lurasidone	Latuda	20-40	40-120	Take with food; ≥350 calories (1,460 Joules)
Olanzapine	Zyprexa	5-10	10-20	Avoid in first episode because of weight gain
Paliperidone	Invega	3-6	3-12	Bioavailability increased when administered with food
Quetiapine	Seroquel	50	300-800	
Quetiapine XR	Seroquel XR	300 mg	400-800	
Risperidone	Risperdal	1-2	2-8	
Ziprasidone	Geodon	40	80-160	Take with food, ≥500 calories (2,100 Joules)

REMS: Risk Evaluation and Mitigation Strategy. XR: extended release.

Note: In first-episode patients, starting dose and target dose should generally be 50% of the usual dose range. See Long-Acting Injectable Antipsychotics in text for dosing of these agents.

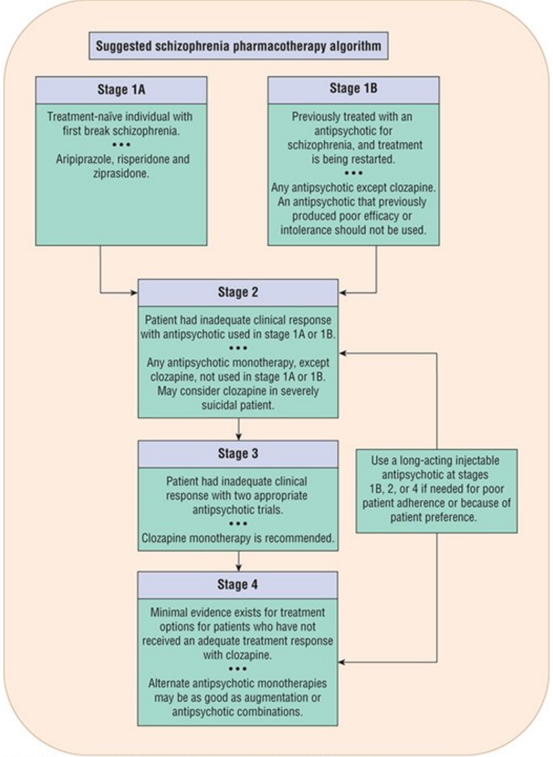
Data from References 24,26-33.

Published Guidelines and an Algorithm Example

⑥ Figure 87-1 outlines a suggested pharmacotherapeutic algorithm for schizophrenia, based on information from four published guidelines, the Psychopharmacology Algorithm Project at the Harvard Medical School Department of Psychiatry South Shore Program,[23] the Canadian Schizophrenia Guidelines,[22] the guidelines from the World Federation of Biological Psychiatry, and the APA Guidelines.[14,22,24]

FIGURE 87-1

Suggested pharmacotherapy algorithm for treatment of schizophrenia. Schizophrenia should be treated in the context of an interprofessional model that addresses the psychosocial needs of the patient, necessary psychiatric pharmacotherapy, psychiatric co-occurring mental disorders, treatment adherence, and any medical problems the patient may have. (See the text for a description of the algorithm stages.)



Suggested schizophrenia pharmacotherapy algorithm
Stage 1A
Treatment-naïve individual with first break schizophrenia.
• • •
Aripiprazole, risperidone and ziprasidone.
Stage 1B
Previously treated with an antipsychotic for schizophrenia, and treatment is being restarted.
• • •
Any antipsychotic except clozapine. An antipsychotic that previously produced poor efficacy or intolerance should not be used.
Stage 2
Patient had inadequate clinical response with antipsychotic used in stage 1A or 1B.
• • •
Any antipsychotic monotherapy, except clozapine, not used in stage 1A or 1B. May consider clozapine in severely suicidal patient.
Stage 3
Patient had inadequate clinical response with two appropriate antipsychotic trials.
• • •
Clozapine monotherapy is recommended.
Use a long-acting injectable antipsychotic at stages 1B, 2, or 4 if needed for poor patient adherence or because of patient preference.
Stage 4
Minimal evidence exists for treatment options for patients who have not received an adequate treatment response with clozapine.
• • •
Alternate antipsychotic monotherapies may be as good as augmentation or antipsychotic combinations.

Stage 1A of the treatment algorithm applies to those patients experiencing their first acute episode of schizophrenia. Use of SGAs during the first acute episode may result in greater treatment retention and effectiveness in preventing a second psychotic episode compared to FGAs. In addition, SGAs carry a reduced risk of EPS.[24] Among the SGAs, aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone have evidence of efficacy in first-episode patients, with lurasidone showing efficacy in adolescents with schizophrenia, but most were not treatment naive.[23,34] Despite its efficacy, olanzapine is not recommended in first episode because of weight gain and adverse metabolic effects.[23,24]

Since quetiapine is associated with less time to rehospitalization compared to other SGAs and causes greater weight gain, some guidelines do not recommend it in stage 1A.[23] This leaves aripiprazole, risperidone, and ziprasidone as the evidence-based options in first-episode patients (stage 1A).[23] Of these, aripiprazole and ziprasidone produce the least weight gain. However, few head-to-head clinical trials have been conducted, and the level of evidence is not sufficiently high to recommend these as the only preferred agents in first episode.[14,22] The 2021 APA Guidelines do not provide any preference among initial antipsychotic selection. Because first-episode patients demonstrate greater sensitivity to adverse medication reactions, antipsychotic dosing should be initiated at the lower end of the dose range.[20,22,23]

In first-episode patients, long-acting risperidone injectable was more effective than oral risperidone in preventing relapse over a one-year period.[35] The relapse rate was six times higher in the oral risperidone group than with the long-acting injectable (LAI); therefore, risperidone LAI can be considered as a treatment option for first-episode patients. If this medication is used, patients should first be stabilized on oral risperidone. It is critical that enriched psychosocial programs be implemented along with appropriate pharmacotherapy.

Stage 1B addresses pharmacotherapy for a patient who was previously treated with an antipsychotic, and treatment is being restarted because the patient stopped taking the medication. If during the initial antipsychotic trial, the patient experienced a robust improvement in symptoms, good tolerability, and is positive about taking this antipsychotic again, then that medication can be restarted. If a different medication is needed, one from stage 2 should be used. Stage 2 addresses pharmacotherapy in a patient who had inadequate clinical improvement with the antipsychotic used in stage 1A or 1B, or the patient responded but subsequently had a relapse while taking the medication. Stage 2 recommends antipsychotic monotherapy with an FGA or SGA not used in stage 1 or stage 1B.[14,22-24] Because of safety concerns and the need for white blood cell (WBC) monitoring, clozapine is not generally recommended at stage 2.[14,22,23] However, clozapine has superior efficacy in decreasing suicidal behavior, and it should be considered at stage 2 for the patient with suicidal thoughts.[22,23] Clozapine can also be considered at stage 2 in patients with a history of violence or comorbid substance use disorder.[22,23,36] If a patient has an unacceptable adverse medication reaction with the antipsychotic used during stage 1A, stage 1B, or stage 2, then an alternate antipsychotic for that stage should be chosen.

Long-acting injectable antipsychotics (LAIAs) should be considered as an option at stage 2. The use of LAIAs should be discussed with the patient as a life style choice, and their use should not be reserved for patients with poor medication adherence. In fact, if a patient prefers receiving a LAIA, it should be considered as an option at Stages 1A, 1B, and 2.[22-24] If there is good documentation of poor symptom improvement with two different antipsychotic trials at appropriate dose and duration, then pharmacotherapy should be initiated with the stage 3 recommended treatment clozapine.[22-24] In stage 4, minimal evidence exists for any treatment option for patients who do not have adequate symptom improvement with clozapine. The Harvard Department of Psychiatry South Shore algorithms present various treatment options for such patients, however, none of these options have conclusive evidence.[23] It is important to note that the use of antipsychotic combinations is controversial, as limited evidence supports increased efficacy for antipsychotic polypharmacy, despite this practice being somewhat common.[22,23] The APA Guidelines state that electroconvulsive therapy (ECT) combined with an antipsychotic may be useful in some patients with treatment resistance.[22]

Predictors of Response

Obtaining a thorough medication history is important, and previous treatment response should help guide antipsychotic selection, in that either a good prior response favors the use of the same agent or a negative prior response suggests the selection of a dissimilar medication. Substance use can influence psychiatric presentation and needs to be considered when making decisions regarding a patient's diagnosis or antipsychotic response. Amphetamines and other CNS stimulants, cocaine, corticosteroids, digitalis glycosides, indomethacin, cannabis, pentazocine, phencyclidine, other medications, and substances can induce psychosis in susceptible individuals or exacerbate psychosis in patients with preexisting psychiatric illness.[1,16,22,23] Patients with schizophrenia who use alcohol or other substances usually have a poor response to medications and a poor overall prognosis. Furthermore, alcohol, cannabis, caffeine, and nicotine use may potentially interact with antipsychotics.

Individual predictors of patient response have been either proposed or identified. Acute onset of symptoms and short duration of illness, presence of acute stressors or precipitating factors, later age of onset, family history of affective illness, and good premorbid adjustment as reflected in stable interpersonal relationships or employment are all predictors of good response.[14]

Although controversial, affective symptoms can correlate with an overall good response, while negative symptoms and neuropsychological deficits related to cognition and neurologic soft signs can correlate with poor antipsychotic response.[14,16,22,23] Subjective positive patient response within the first 48 hours after FGA administration can be associated with medication responsiveness,[37] whereas an initial dysphoric response, demonstrated by stating a dislike of the medication, feeling worse or "zombie-like," anxiety or akathisia-like symptoms, is associated with poor medication response, adverse effects, and nonadherence.

The importance of developing a therapeutic alliance between the patient and the clinician cannot be underestimated (see Chapter e81, "Evaluation of Psychiatric Illness"). Patients who form positive therapeutic alliances are more likely to be adherent with all aspects of therapy, experience a better outcome at 2 years, and require lower antipsychotic doses.[20] However, a certain minority of patients fail to benefit from antipsychotic therapy, and their psychosocial functioning can worsen with antipsychotic continuation.

Initial Treatment in an Acute Psychotic Episode

The goals during the first 7 days of treatment should be decreased agitation, hostility, combativeness, anxiety, tension, and aggression, and normalization of sleep and eating patterns. The usual recommendation is to initiate therapy and to titrate the dose over the first few days to an average effective dose, unless the patient's physiologic status or history indicates that this dose can result in unacceptable adverse medication reactions. Because of strong alpha-1 (α_1) receptor antagonism and resulting risk of hypotension, iloperidone and clozapine should be titrated more slowly than other SGAs. Rapid titration to high doses is not recommended. Table 87-2 lists the usual dosage range, with an average dose typically being midrange.[14,22-24] Because patients with first-episode psychosis have an increased sensitivity to adverse medication reactions, particularly EPS, typical dosing ranges are approximately 50% of the doses used in chronically ill individuals.[22,23] If "cheeking" of medication is suspected (where the patient places the medication in their cheek and then spits it out later), liquid formulations and orally disintegrating tablets are available for some antipsychotics. If a patient has no improvement after 2 weeks at a therapeutic dose, then later clinical response is unlikely, and moving to the next treatment stage of the algorithm is recommended.[38]

Although some clinicians believe that larger daily doses are necessary in patients with more severe symptoms, data do not support this practice. Some symptoms, such as agitation, tension, aggression, and increased motor activity, may respond more quickly, but adverse medication reactions can be more common with higher doses. However, interindividual differences in dosage and response do occur. In patients with partial response who are tolerating the chosen antipsychotic, it may be reasonable to titrate above the usual dose range. However, this tactic should be time-limited (ie, 2-4 weeks), and if the patient does not achieve further improvement, either the dose should be decreased or an alternative treatment strategy should be tried. As previously stated, rapid titration of antipsychotic dosage is not indicated[14,22-24]; however, intramuscular (IM) antipsychotic administration (eg, haloperidol 2-5 mg IM, olanzapine 2.5-10 mg IM, or ziprasidone 10-20 mg IM) can be used to assist in calming a patient with severe agitation. Clinically, agitation can manifest as loud, physically or verbally threatening behavior, motor hyperactivity, or physical aggression. Although use of IM antipsychotics can assist in calming a patient with acute agitation due to psychosis, it does not improve the rate of remission, time to remission, or the length of hospitalization. Haloperidol (an FGA) given IM for treatment of acute aggression is associated with a higher incidence of EPS than IM SGAs. If the patient is receiving an antipsychotic within the usual therapeutic range, the use of lorazepam 2 mg IM as needed in combination with the maintenance antipsychotic is a rational alternative for treatment of aggression. Hypotension, respiratory depression, CNS depression, and death have been reported with injectable lorazepam in combination with either olanzapine or clozapine; thus, injectable lorazepam is not recommended in combination with either of these medications.[24]

Inhaled loxapine powder is Food and Drug Administration (FDA) approved for treatment of acute agitation associated with schizophrenia or bipolar disorder. Because of the risk of bronchospasm, pulmonary distress, and pulmonary arrest, the medication can only be administered in a healthcare facility through the FDA-approved Risk Evaluation and Mitigation Strategy (REMS). Before administration, patients must be screened for a history of asthma, chronic obstructive pulmonary disease, or other lung disease associated with bronchospasm, and use is limited to one 10 mg inhaled dose per 24-hour period.[26] Whether inhaled loxapine offers any therapeutic advantages in acute agitation compared with other antipsychotics is unknown, and patients must be sufficiently cooperative to inhale it appropriately.

Stabilization Therapy

⑦ Symptom improvement may occur over 6 to 12 weeks with appropriate medication therapy and comprehensive treatment. During the first 2 to 3 weeks, goals should include increased socialization and improvement in self-care habits and mood. Improvement in any formal thought disorder should follow and may take an additional 6 to 8 weeks. Patients who are early in the course of their illness tend to experience a more rapid resolution of symptoms than individuals who are more chronically ill. In general, if a patient has shown no improvement after 2 weeks of treatment at therapeutic doses, or has achieved only a partial decrease in positive symptoms within 8 to 12 weeks at adequate doses, then the next algorithm stage should be considered. In more chronically ill patients, symptoms may continue to improve over 3 to 4 months. Quantifying symptom change using a brief symptom rating scale can be helpful in monitoring treatment and making decisions. An optimum target medication dose should be estimated in the initial treatment plan. If the patient begins to show adequate response at a dose, then the patient should remain at this dosage if symptoms continue to improve. In general, adequate time on a therapeutic antipsychotic dose is the most important factor in predicting medication response. However, if necessary, dose titration can continue within the therapeutic range every 1 or 2 weeks if the patient has no adverse medication reactions.

Before changing medications in a patient with poor response, the following should be considered: Were the initial target symptoms indicative of schizophrenia or did they represent manifestations of a different diagnosis, a long-standing behavioral problem, a substance use disorder, or a general medical condition? Is the patient adherent with pharmacotherapy? Are the persistent symptoms poorly responsive to antipsychotics (eg, impaired insight or judgment, or fixed delusions)? How does the patient's current status compare with response during previous exacerbations? Would this patient potentially benefit from advancing to a different treatment stage (Fig. 87-1)? Does this patient have treatment-resistant schizophrenia?

The conclusion that the patient with a partial response has achieved as much symptomatic improvement as possible is one that must be made with great care as treatment goals must be realistic. Medications are effective in decreasing many of the symptoms of schizophrenia (and are thus referred to as palliative), but they are not curative, and not all symptoms may abate. Although one should aim to achieve full remission to minimal residual positive symptoms, it is still unclear what a realistic goal is regarding maximum improvement in negative symptoms.

It is important to screen patients for co-occurring psychiatric disorders, and their presence can become more apparent during the stabilization or maintenance phases of treatment. Examples include substance use disorders, depression, obsessive-compulsive disorder, and panic disorder. As co-occurring disorders will limit symptom and functional improvement and increase the risk of relapse. It is critical that treatment for the co-occurring disorder be implemented in combination with evidence-based treatment for schizophrenia.

Maintenance Treatment

Maintenance medication therapy prevents relapse, as shown in numerous double-blind studies, which is a major goal of treatment.[14,22-24] The average relapse rate after 1 year is 18% to 32% with active medication (including some patients with nonadherence) versus 60% to 80% for placebo.[14,22-24]

⑧ After treatment of the first psychotic episode in a patient with schizophrenia, medication should be continued for at least 18 months after remission.[14,22-24] Many experts recommend that patients with robust medication response be treated for at least 5 years; however, in chronically ill individuals, continuous or lifetime pharmacotherapy is necessary in most patients to prevent relapse. This practice should be approached with the lowest effective antipsychotic dose that is tolerated by the patient.[14,22-24]

Antipsychotics should be tapered slowly before discontinuation as abrupt discontinuation, especially with clozapine, can result in withdrawal symptoms, felt to be a manifestation of rebound cholinergic outflow. Insomnia, nightmares, headaches, gastrointestinal symptoms (eg, abdominal cramps, stomach pain, nausea, vomiting, and diarrhea), restlessness, increased salivation, and sweating are reported. Although available evidence does not indicate a best way to switch from one antipsychotic to another, it is often recommended to taper and discontinue the first antipsychotic over at least 1 to 2 weeks while the second antipsychotic is initiated and the dose titrated.[24] Tapering needs to occur more slowly with clozapine.[38]

Long-Acting Injectable Antipsychotics

Early studies did not consistently demonstrate an advantage of LAIAs over oral agents. However, studies, designed to reflect real-world practices, have more consistently demonstrated an advantage in reduced hospitalizations and relapse prevention in patients with schizophrenia, findings that were confirmed in a meta-analysis.[39,40] Despite the potential advantages, the use of LAIAs is relatively low compared with oral antipsychotics, and in most Western countries use falls below 20%.[41] Barriers to LAIA use may be clinician or patient driven and include: biases and attitudes, limited insurance coverage, or lack of experience with LAIAs.[42] Traditionally, LAIAs have been primarily used later in the course of treatment and in patients who are unreliable in taking oral medication. It has been suggested to offer LAIAs to patients as a treatment option earlier in their disease before they develop a pattern of nonadherence.[41,42] For example, they can be presented to a patient as a life style option, in which the patient does not need to take a medication daily.[22] Normalizing the use of LAIAs, providing appropriate education to families and patients on LAIAs, utilizing motivational interview techniques, and offering it as an early treatment option may aid in improving LAIA acceptability with patients.[39]

Treatment nonadherence rates as high as 60% in patients with schizophrenia can lead to negative clinical outcomes.[41] Nonadherence can be due to several factors including cognitive impairment, persistent symptoms, substance use, or lack of insight. However, before declaring a patient as nonadherent, it should be determined whether the patient is experiencing adverse medication reactions. If so, an alternative medication with better tolerability should be considered before initiating a LAIA. The patient's motivation for treatment is a major factor influencing outcome.

There are ten LAIAs available for use in the United States: risperidone (two different formulations), paliperidone palmitate (three formulations), aripiprazole (monohydrate and lauroxil), olanzapine pamoate, haloperidol decanoate, and fluphenazine decanoate. Conversion from an oral antipsychotic to a LAIA should start with stabilization on an oral dosage form of the same agent for a short trial (4-14 days) to determine whether the patient tolerates the medication without significant adverse medication reactions, especially if the patient has no previous exposure to the oral agent.[39]

With risperidone microspheres (Consta®), measurable serum concentrations are not seen until approximately 3 weeks after single-dose administration. Thus, it is important that the oral antipsychotic be administered for at least 3 weeks after the first injection. The recommended starting dose with risperidone microspheres is 25 mg. Clinical experience suggests that titration to doses greater than or equal to 37.5 mg per injection may be necessary for maintenance treatment; however, efficacy was demonstrated with doses of 25 to 50 mg IM every 2 weeks. Dose adjustments are recommended to be made no more often than once every 4 weeks.[43] Doses above 50 mg every 2 weeks are not recommended, as research indicates no greater clinical efficacy but more EPS.[25] With risperidone extended-release injectable suspension (PERSERIS®), dosing is 90 or 120 mg once monthly, no oral overlap or loading dose is necessary, and it is the only LAIA that is administered subcutaneously in the abdomen.[44]

Paliperidone palmitate (Invega Sustenna®) has the advantage of easy conversion from oral paliperidone to IM treatment, as there is no need for oral overlap, and this formulation offers once-monthly injections with the option to convert to 3-month or 6-month formulations.[43] It is initiated with 234 mg on day 1 and 156 mg a week later (+/− 4 days) with deltoid administration for the first two doses as gluteal absorption results in 28% lower C_{max}. The 1-month paliperidone palmitate (1MPP) IM doses are then titrated according to response within a range of 39 to 234 mg and can be injected into either the deltoid or gluteal muscle.[43] If a patient's oral paliperidone is established prior to converting to the 1MPP, the maintenance dose required for similar paliperidone exposure is outlined in Table 87-5.[45]

A 3-month paliperidone palmitate (3MPP, Invega Trinza®) and 6-month paliperidone palmitate (6MPP, Invega Hafyera) LAIA are approved for the management of schizophrenia, with both formulations being found to significantly delay time to relapse compared with placebo. The 3MPP and 6MPP provide the longest dosing interval available, but require patients to be treated for at least 4 months with 1MPP prior to 3MPP initiation. Those who have received at least one dose of the 3MPP may be converted to the 6MPP. The first 3MPP dose is based on the previous 1 month injection dose, and the first 6MPP dose is based on either the 1- or 3-month injection dose, as shown in Table 87-3.[46]

TABLE 87-3

Summary of Available Long-Acting Injectable Antipsychotics (LAIAs)

Medication Name		Fluphenazine Decanoate	Haloperidol Decanoate	Risperidone (Risperdal Consta)	Risperidone (PERSERIS)	Paliperidone Palmitate (Invega Sustenna) (1MPP)	Paliperidone Palmitate (Invega Trinza) (3MPP)	Paliperidone Palmitate (Invega Hafyera)(6MPP)	Olanzapine Pamoate (Zyprexa Relprevv)	Aripiprazole Monohydrate (Abilify Maintena)	Aripiprazole (Lauroxil Aristada®)
Dose Range (mg)		12.5-100	20-450	12.5-50	90-120	39-234	273-819	1,092-1,560	150-405	300-400	441-882[b]
PO Overlap		None	4 weeks (none if loading); use PO dose patient was taking prior to injection	3 weeks after first injection: use PO dose patient was taking prior to injection	None	None	None	None	None	2 weeks PO dose ranges from 10 to 20 mg/day	21 days PO overlap after first injection
Recommended maximum dose		100 mg every 2-3 weeks	450 mg every 4 weeks	50 mg every 2 weeks	120 mg monthly	234 mg every 4 weeks	819 mg every 3 months	1,560 mg every 6 months	300 mg every 2 weeks or 405 mg every 4 weeks	400 mg monthly	882 mg monthly
Initiation or Loading		Can Load	Can Load	None	None	Initiation required	None required, dose based on last Invega Sustenna dose: If 78 mg give 273 mg If 117 mg give 410 mg If 156 mg give 546 mg If 234 mg give 819 mg	None required, dose used depends on last Invega Sustenna or Trinza dose For Invega Sustenna: If 156 mg give 1,092 mg If 234 mg give 1,560 mg For Invega Trinza: If 546 mg give 1,092 mg If 819 mg give 1,560 mg	Initiation required	None	None required, dose based on PO dose: If 10 mg/day give 441 mg If 15 mg/day give 662 mg If 20 mg give 882 mg
Time to peak		8-24 hours	4-11 days	4-5 weeks	4-6 hr	13 days	30-33 days	29-32 days	<1 week	5-7 days	5-6 days
T_{ss}		2-3 months	2-3 months	6-8 weeks	60 days	7-11 months	Continues steady-state	Continues steady-state	3 months	3-4 months	4 months
Half-life		14 ± 2[a] days	21 days	3-6 days	9-11 days	25-49 days	84-89 days (deltoid) 118-139 days (gluteal)	148-159 days	30 days	30-47 days	29-35 days
Injection Site	Gluteal	Yes	Yes	Yes	Abdominal only	Yes after 2nd dose	Yes	Yes	Yes	Yes	Yes
	Deltoid	Yes	Yes	Yes		Yes	Yes	No	No	No	Yes, but only 441 mg dose
Injection Method/Technique		Z-Track	Z-Track			Subcutaneous Injection					
Notes				A starting dose of 12.5 mg is recommended in patients with hepatic or renal impairment	90 mg = 3 mg PO Risperidone 120 mg = 4 mg PO Risperidone	Avoid use in patients with moderate-to-severe renal impairment (CrCl <50 mL/min [0.83 mL/s])	Requires at least a 4-month trial with 1MPP. Not recommended in patients with moderate or severe renal impairment (CrCl <50 mL/min [0.83 mL/s])	Requires at least a 4 month trial with 1MPP or at least 1 cycle of 3MPP. Not recommended in patients with moderate or severe renal impairment (CrCl <50 mL/min [0.83 mL/s])	Monitor for PDSS Subject to REMS	Maintenance dose reduced to 300 mg if patient experiences adverse events. Dose adjustment needed in CYP2D6 slow metabolizers. Avoid use in patients taking CYP 3A4 inhibitors >14 days	May require 2 week PO trial to establish efficacy before initiating LAIA Avoid use of strong CYP2D6 and 3A4 inhibitors for 662 and 882 mg dose, no adjustment needed for 441 mg dose

CrCl, creatine clearance; IM, intramuscular; LAIA, long-acting injectable; PO, oral; Tss, time to steady state.

[a]Based on multiple-dose data. Single-dose data indicate a β-half-life of 6-10 days.

[b]Additional dosing regimens include extended intervals up to 1,064 mg every 8 weeks; loading protocol with Aristada Initio 675 mg + maintenance Aristada dose + PO 30 mg x1 dose does not require PO overlap

Data from References 38, 43, 47-49, 45, 46, 50-52, and 48.

Olanzapine pamoate monohydrate is a LAIA administered every 2 or 4 weeks that does not require oral overlap. It is recommended for deep gluteal injection, and the initial injectable dose varies from 210 to 405 mg depending on the oral olanzapine daily maintenance dose and the frequency of injectable administration.[43,50] A disadvantage to olanzapine pamoate is its association with post-injection delirium/sedation syndrome (PDSS) occurring in <2% of patients.[50] The symptoms of PDSS are similar to those of an oral olanzapine overdose and include delirium, ataxia, confusion, heavy sedation, or altered levels of consciousness. Although PDSS can occur with any dose and at any time during treatment, most cases have occurred within the first three injections.[51] The most likely explanation for the occurrence of PDSS is an accidental intravascular injection resulting in the medication dissolving more rapidly and sharp increases in plasma levels.[51,52] The product labeling contains an FDA-boxed warning regarding PDSS, and olanzapine pamoate is subject to a REMS with the FDA labeling limiting the availability of olanzapine LAIA to a restricted distribution program. The injection must be administered in a registered healthcare facility, and the patient must be observed by a health professional for at least 3 hours after administration and must not drive or operate machinery that day.[50]

Aripiprazole monohydrate LAIA (Abilify Maintena) is administered as a single intramuscular injection in the gluteal or deltoid muscle once a month at a starting and maintenance dose of 400 mg. If the patient does not tolerate the 400 mg dose, the next injection can be reduced to 300 mg. After the first injection of aripiprazole monohydrate LAIA, a 14-day overlap with oral aripiprazole (10-20 mg/day) or any other antipsychotic is recommended.[43] Aripiprazole lauroxil LAIA (Aristada) is administered as a single intramuscular injection in the deltoid (441 mg only) or gluteal (441, 662, or 882 mg, once a month). The 882 mg dose can be administered every 6 weeks and the 1,084 mg every 2 months. Aripiprazole lauroxil has the advantage of having initiation dosing available (Aristada Initio)[47]; however, if Aristada Initio is not utilized, oral overlap is required for 3 weeks with this LAIA formulation.[52]

For the FGA fluphenazine decanoate, the simplest dosing conversion method recommends 1.25 times the oral fluphenazine daily dose for stabilized patients, rounding to the nearest 12.5 mg interval, which is administered in weekly doses for the first 4 to 6 weeks; or 1.6 times the oral daily dose given weekly for the first 4 weeks for more acutely ill patients.[48] Subsequently, fluphenazine decanoate can be administered once every 2 to 3 weeks. Although oral fluphenazine can be overlapped for 1 week, the dose should be reduced by half with the first injection to reduce the risk of EPS.[48] For haloperidol decanoate, the first dose should be 10 to 20 times the oral haloperidol daily dose. In patients who are at high risk of relapse, and are tolerant to oral haloperidol, a loading dose of 20 times the oral dose can be considered.[48] In patients naïve to haloperidol decanoate, the initial injection is limited to 100 mg followed by the remaining balance of the first monthly dose given 3 to 7 days later.[43] Overlap with oral haloperidol overlap is not necessary if the patient receives a loading dose, but is recommended for the first month if a loading dose strategy is not utilized. The maintenance dose is typically 10 to 15 times the oral dose once monthly. Table 87-3 provides a summary of the LAIAs.

Methods to Enhance Patient Adherence

Treatment nonadherence rates are as high as 60% in patients with schizophrenia, which can lead to negative clinical outcomes.[41] If nonadherence is suspected, the clinician should ask in a nonjudgmental manner if the patient is having any difficulty taking their medication and then the reason for nonadherence should be determined. If nonadherence is occurring because of adverse effects, then a medication with a more favorable tolerability profile should be considered. Suspected nonadherence can also be assessed by obtaining an antipsychotic serum concentration.[53]

Maintaining appropriate medication adherence is often challenging for individuals with chronic illnesses and partial adherence is a reality and should be expected to be the norm.[24] Individuals with serious psychiatric disorders have higher nonadherence rates than those with general medical disorders, with the following explanations provided: denial of illness, lack of insight, grandiosity or paranoia, no perceived need for medication, perceived lack of input into choice of medication or dosage, adverse medication reactions, misperceived "allergies," too many medications prescribed, or too many doses prescribed daily (see Table 87-4). It is estimated that half of patients with schizophrenia or schizoaffective disorder take their medication less than 70% of the time.[24] Discussions regarding this topic should be approached in a positive, nonjudgmental manner, with the clinician actively engaging the patient in care and using motivational interviewing techniques as mechanisms to enhance therapeutic alliance and patient adherence.

TABLE 87-4

Nonadherence with Antipsychotic Medications Is a Multidimensional Dilemma

Patient factors	Medication Factors	Other factors
Lack of insight Paranoia Attitude to medications Prior experiences Perception of efficacy of medication Comorbid substance use disorder	Efficacy Adverse medication reactions Mode of delivery/ingestion Cost Availability	Family perspectives Cultural influences Clinician perspectives and influences Insurance coverage Cost of care Medication access and support Mental illness stigma

Data from References 54 and 55.

⑨ Numerous different methods have been used to improve treatment adherence of patients with schizophrenia. Interventions that provide continuous focus on adherence and that are of long duration have shown benefit. These should incorporate problem-solving techniques and be accompanied by technical learning aids. As previously noted, programs need to include a focus on patient-driven outcomes, and not just medication adherence, and interventions should include efforts to allow patients to achieve life goals and function. This requires that programs be tailored to the needs of individual patients.[54] Psychoeducation strategies should include motivational interviewing techniques in individual counseling as well as group activities.

Compliance therapy, targeted cognitive behavioral therapy focusing on medication adherence, can improve patient adherence, but the success seen in early studies has not been consistently replicated.[54]

Groups facilitated by trained individuals who have the illness are thought to be more effective in enhancing awareness and acceptance of schizophrenia and necessary treatment, than groups led only by professionals. Active involvement of family members further increases the likelihood of patient adherence with treatment. In addition to programs provided by community mental health centers, support groups operated by consumer groups such as the National Alliance on Mental Illness (NAMI) are available for patients and their families in most urban areas. In the hospital, self-medication administration can reinforce the patient's perception of his or her active role in treatment. When patients miss outpatient appointments, active outreach interventions must be implemented to enhance patient engagement in treatment.[54]

The LAIAs have been a mainstay of treatment for people who are nonadherent with taking oral medications. However, for various reasons, they are used in only a relatively small subset of patients, and many patients simply do not like getting injections. Abilify MyCite, an FDA-approved technology, includes a biosensor inside the aripiprazole tablet; after the medication is ingested, the coating is degraded and a specific patch worn by the patient picks up a biosensor signal from the formulation.[49] Data are then transferred to a smart phone application and can be shared by the patient with the treating clinician via the internet. It is not clear whether this technology improves patient adherence in a population that is often suspicious and paranoid. Regardless, a great deal of education is necessary to make sure that the patient knows how to use the technology and to assure that the patient wears the patch and uses the smart phone application correctly.

Management of Treatment-Resistant Schizophrenia

In general, "treatment resistant" describes a patient who has had inadequate symptom response from multiple antipsychotic trials.[22-24,53] The clinical definition of treatment resistance requires persistent symptoms of at least moderate severity, despite treatment with two different antipsychotics at adequate dosage for at least 6 weeks each with good treatment adherence.[53] Between 10% and 30% of patients receive minimal symptomatic improvement after multiple antipsychotic monotherapy trials.[22-24] An additional 30% to 60% of patients have partial but inadequate improvement in symptoms or unacceptable adverse medication reactions associated with antipsychotic use. In patients not responding to two or more pharmacotherapy trials, a treatment-refractory evaluation should be performed to reexamine diagnosis, substance use, medication adherence, and psychosocial stressors. Targeted cognitive behavioral therapy or other psychosocial augmentation strategies should be considered.[22,23] While clozapine remains the treatment of choice for treatment-resistant schizophrenia, its use has declined over time in favor of sequential treatment trials of SGAs. This is problematic and trainees need exposure to initiating clozapine therapy, given the low likelihood of later use in clinical practice without this experience.

Clozapine

Only clozapine has shown superiority over other antipsychotics in randomized clinical trials for the management of treatment-resistant schizophrenia as most other SGAs have either not been studied in this patient population, or have been evaluated in small open trials. In a seminal study, clozapine was effective in approximately 30% of patients with treatment-resistant schizophrenia, compared with only 4% treated with a combination of chlorpromazine and the anticholinergic benztropine.[56] Other candidates for clozapine include those patients with severe suicidality, aggressive behavior, or those who cannot tolerate neurologic adverse medication reactions from conservative doses of other antipsychotics.

Symptomatic improvement with clozapine in the treatment-refractory patient often occurs slowly, and as many as 60% of patients continue to improve if clozapine is used for up to 6 months. This, in combination with clozapine's tolerability profile, provides sufficient information to conclude that clozapine is not a panacea for schizophrenia. Polydipsia and hyponatremia (psychogenic water drinking) is a frequent problem among treatment-refractory patients, and clozapine reportedly decreases water drinking and increases serum sodium in such patients.[23,24]

Because of the risk of orthostatic hypotension, clozapine is usually titrated more slowly than other antipsychotics, particularly on an outpatient basis. If a 12.5-mg test dose does not produce hypotension, then clozapine 25 mg at bedtime is recommended, increased to 25 mg twice a day after 3 days, and then increased in 25 to 50 mg/day increments every 3 days until a dose of at least 300 mg/day is reached. If tolerated, a minimum trial should be 3 months with a clozapine serum concentration of at least 350 ng/mL (mcg/L; 1.07 µmol/L). Because high doses are associated with significantly increased adverse medication reactions, including seizures, a clozapine serum concentration is recommended before exceeding 600 mg/day.[24] If the clozapine serum concentration is greater than 350 ng/mL (mcg/L; 1.07 µmol/L), then further dosage increases are not indicated.[53]

Augmentation and Combination Strategies

Limited empirical evidence exists to guide treatment decisions for patients who do not respond to clozapine.[22–24] Current strategies include augmentation with a non-antipsychotic medication in patients with poor or partial response, or combination treatment using two antipsychotics simultaneously.

In a small, single blind, randomized trial, 50% of patients demonstrated clinically significant improvement in symptoms with electroconvulsive therapy (ECT) augmentation of clozapine, compared with no responders in the clozapine monotherapy group. When the patients in the clozapine monotherapy group received ECT, 47% demonstrated clinically significant improvement.[23]

Mood stabilizers are frequently used as an augmentation strategy, and while lithium does not enhance the antipsychotic effect, it may improve labile affect and agitated behavior in select patients.[23] Enzyme induction with carbamazepine can cause a decrease in antipsychotic serum concentrations and potentially worsen psychotic symptoms in some patients.[23,57]

Only limited data are available to support antidepressant augmentation of antipsychotics.[22-24] However, consistently positive results have been reported when using selective serotonin reuptake inhibitors (SSRIs) to treat obsessive-compulsive symptoms that worsen or arise during clozapine treatment.

Combining an FGA with an SGA and combining different SGAs have been suggested as intervention strategies for treatment-resistant patients. Pharmacodynamically, there is limited rationale to explain how combinations of antipsychotics would produce enhanced efficacy, but increased adverse medication reactions, particularly increased EPS, metabolic effects, and hyperprolactinemia, are possible results.[22] The evidence to support antipsychotic combinations is scant. However, a large Finnish database study, using patients as their own controls, found that clozapine plus aripiprazole had a lower rehospitalization rate than any other monotherapy or combination antipsychotic treatment.[58] This observational study was not in patients identified as treatment resistant. Regardless, this topic remains highly contentious, and clinicians' practice is often not aligned with available evidence. Moreover, the availability of new treatment options can result in combination therapies being tried with antipsychotics with insufficient scientific evidence. This approach further complicates the application of systematic, evidence-based treatments for schizophrenia. In general, a series of antipsychotic monotherapy courses, including clozapine, are preferred over antipsychotic combinations.[22] However, when clozapine fails to produce desired outcomes, a time-limited combination trial is sometimes considered (eg, maximum 12 weeks) with the patient carefully evaluated using standardized rating scales to assess symptomatology.[23] If no apparent improvement is observed, then one of the medications should be tapered and discontinued. However, if the patient has a partial response (greater than or equal to 20% improvement in positive symptoms) after 12 weeks with combination treatment, medications should be titrated to doses at the upper end of the therapeutic range, and treatment should continue for an additional 12 weeks before a change in treatment is considered.

Violence in Schizophrenia

Most people with schizophrenia do not exhibit violent behavior; however, they are more likely to be violent than the general population. The rate of violence in people with schizophrenia is 9.9% compared with 1.6% in the general population.[36] Risk factors for violence include those associated with violence in the general population (eg, childhood trauma and exposure to violence, alcohol and substance use disorders, psychopathy, and access to firearms) and (to lesser extent) psychotic symptoms.[36] Most of the risk of violence is associated with co-occurring substance use disorders.[36] Patients are at risk to become violent when they relapse and so keeping patients clinically stable is a major consideration. Clozapine has been found to be superior to other antipsychotics in decreasing aggressive and violent behavior.[36] Some states have outpatient commitment laws where patients at risk of violence are "forced" to get ongoing care, and if they default, they are sent back to the hospital. Patients who are dangerous are invariably managed either in the legal system itself or legally as "forensic" patients where they are held by court order in a psychiatric facility.

Antipsychotic Mechanism of Action

The exact mechanism of actions of antipsychotics are unknown. Antipsychotics is classified into three different categories: (a) typical (traditional or FGAs) (high D_2 antagonism and low serotonin-2 receptor [5-HT_{2A}] antagonism); (b) atypical (SGAs) (moderate-to-high D_2 antagonism and high 5-HT_{2A} antagonism); and (c) atypical clozapine-like (low D_2 antagonism and high 5-HT_{2A} antagonism).[59] With the exception of aripiprazole and brexpiprazole, all current SGAs have a greater affinity for 5-HT_{2A} receptors than D_2 receptors, and brexpiprazole shows stronger antagonism of the 5-HT_{2A} receptor than aripiprazole.[59,60] Brexpiprazole also demonstrates higher affinity for the serotonin-1A (5-HT_{1A}) receptor compared to aripiprazole but with less intrinsic D_2 activity than aripiprazole.[60]

Prospective studies of antipsychotic receptor binding in humans have used PET scans to examine neurotransmitter receptor binding 12 hours post-dose in small numbers of individuals at steady-state concentrations. It has been proposed that at least 60% to 65% D_2 receptor occupation is necessary to decrease positive psychotic symptoms, whereas blockade of approximately 77% or more of D_2 receptors is associated with EPS.[59] Table 87-5 outlines the relative differences in receptor binding for various agents. In general, all FGAs are DA receptor antagonists with high affinity for D_2 receptors, and during chronic treatment, between 70% and 90% of D_2 receptors in the striatum are usually occupied. In contrast, during clozapine treatment only 38% to 47% of D_2 receptors are occupied, even with high doses. Newer SGAs have variable D_2 binding. Low D_2 binding seen with the SGAs, can be directly associated with how rapidly the antipsychotic disassociates from the D_2 receptor.[59] This transient blockade of DA receptors may be adequate to produce antipsychotic effect, but longer term D_2 blockade is required for production of EPS and sustained hyperprolactinemia. Aripiprazole and brexpiprazole are partial agonists at D_2 receptors, and represent a further elaboration of the DA hypothesis of antipsychotic action.[59,60]

Relative neuroreceptor binding affinities of select antipsychotics.

(-) = minimal or none; (+) = low; (++) = moderate; (+++) = high; (++++) = very high

Data from References 61 and 62.

Iloperidone's pharmacology is different in that it has high affinity for D_2, dopamine-3 (D_3), and 5-HT_{2A} receptors, and moderate affinity for dopamine-4 (D_4), serotonin-6 (5-HT_6), serotonin-7 (5-HT_7), and α_1-receptors.[27] Asenapine has high affinity for 5-HT_{2A} and D_2 receptors as well as for α_1- and histamine-1 receptors with D_2 occupancy approximating 80% with a sublingual dose of 5 to 10 mg twice daily.[28] Cariprazine has high affinity for D_2 and D_3 receptors as a partial agonist, with the D_3 potency being significantly greater than D_2. It is also a partial agonist at 5-HT_{1A} receptors and an antagonist at serotonin-1B (5-HT_{1B}) receptors.[29] Therefore, given all of these different mechanisms of action, our understanding of the manner in which they produce a clinical profile is still in its infancy.

With low-dose risperidone (2-5 mg/day), D_2 binding ranges from 60% to 79%, but with doses greater than 6 mg daily, binding commonly exceeds the 77% threshold associated with the development of EPS. Risperidone 2 mg/day produces 5-HT_{2A} binding greater than 70%, and with 4 mg/day it is nearly 100%.[59] Olanzapine 10 to 20 mg/day produces D_2 binding ranging from 71% to 80%, whereas at 30 to 40 mg/day, it ranges from 83% to 88%. At 5 mg/day, 5-HT_{2A} receptors are near saturation of binding.[59] Ziprasidone has the highest 5-HT_{2A}-to-D_2 affinity ratio of any of the currently available antipsychotics. It is also a potent serotonin-1A (5-HT_{1A}) agonist.[59]

Quetiapine has the lowest D_2 binding. At doses of 300 to 600 mg/day, 12-hour post-dose D_2 binding ranges from 0% to 27%. Even at quetiapine 800 mg/day, only 30% of D_2 receptors are occupied. At these same daily doses, 45% to 90% of 5-HT_{2A} receptors are occupied. However, when quetiapine D_2 binding is examined 2 to 3 hours post-dose, 58% and 64% of receptors were occupied with 400 and 450 mg, respectively.

Lumateperone is a moderate antagonist at both D_1 and D_2 receptors and a potent antagonist at 5-HT_{2A} receptors. In individuals with schizophrenia, lumateperone occupied approximately 42% of D^2 receptors. It is also a presynaptic DA agonist and a 5-HT reuptake inhibitor. It indirectly modulates glutamatergic activity resulting in increased NMDA and AMPA activity.[33,62]

The primary therapeutic effects of antipsychotics are thought to occur in the limbic system, including the ventral striatum, whereas EPS are thought to be related to DA blockade in the dorsal striatum. For SGAs, 5-HT_{2A} antagonism in combination with modest D_2 blockade leads to release of DA in the prefrontal cortex, and this is one explanation for the decrease in negative symptoms and improvement in cognition reported with these antipsychotics.[48] Medications that are not D_2 antagonists are currently in clinical trials for the treatment of schizophrenia. If these medications are approved by the FDA, they may have a significant effect on how we look at antipsychotic mechanisms of action and efficacy.

As discussed, antipsychotics vary in their effects on other neurotransmitter receptor systems.[59] Although the significance of these different mechanisms on efficacy is unclear, they do potentially explain differences in adverse medication reaction profiles. These differences in pharmacodynamics profiles point out that the SGAs are not alike, and patients obtaining an inadequate clinical response (either efficacy or adverse medication reactions) with one antipsychotic may have a superior response/tolerability on an alternate medication. Thus, serial SGA monotherapy trials should be tried in patients receiving a suboptimal clinical response (see Fig. 87-1).

Pharmacokinetics

As a class, antipsychotics are highly lipophilic and highly bound to membranes and plasma proteins. They distribute readily into most tissues with a high blood supply and can accumulate in tissues; therefore, they have large volumes of distribution.[63] Most antipsychotics are largely metabolized, primarily through the cytochrome P450 (CYP) pathways in the liver, except for ziprasidone, which is largely metabolized by aldehyde oxidase. Fluphenazine and perphenazine are metabolized through CYP2D6, and thus are susceptible to pharmacogenetically regulated metabolism.[64] This is also one of the major pathways for the metabolism of aripiprazole, brexpiprazole, haloperidol, iloperidone, and risperidone.[64] Thirty percent to 35% of people of African and Asian descent are slow to intermediate CYP2D6 metabolizers, and approximately 0% to 5% of African American, 1% of Asian, and 5% to 10% of White populations are poor metabolizers.[65] In addition, some people of Swedish descent and up to 30% of those from Northern Africa may be ultra-rapid CYP2D6 metabolizers.[66] Genetic variation within CYP1A2 can potentially result in a decrease in the metabolic rate of clozapine, whereas, smoking may increase clozapine and olanzapine metabolism due to the effect of cigarette smoke inducing CYP1A2 linked to a specific genotype.[64,65] Pharmacogenomics should be considered when dosing and monitoring the clinical effects of antipsychotics.[64-66] Additional resources related to specific gene and drug pairs for pharmacogenomics information can be obtained at the Clinical Pharmacogenomics Implementation Consortium (CPIC) Website (www.cipicpgx.org). Table 87-6 outlines the prominent metabolic pathways of selected antipsychotics.

TABLE 87-6

Pharmacokinetic Parameters of Selected Antipsychotics

Medication	Bioavailability (%)	Half-Life	Major Metabolic Pathways	Active Metabolites
Selected First-Generation Antipsychotics (FGAs)				
Chlorpromazine	10-30	8-35 hr	FMO3, CYP3A4	7-Hydroxy, others
Haloperidol	40-70	12-36 hr	**CYP2D6**, CYP1A2, CYP3A4	Reduced haloperidol
Perphenazine	20-25	8.1-12.3 hr	**CYP2D6**	7-OH-perphenazine
Second-Generation Antipsychotics (SGAs)				
Aripiprazole	87	48-68 hr	**CYP2D6, CYP3A4**	Dehydroaripiprazole
Asenapine	<2 orally 35 SL Nonlinear	13-39 hr	**CYP1A2, UGT1A4**, CYP2D6, CYP3A4	None known
Brexpiprazole	95	91 hr	**CYP2D6, CYP3A4**	DM-3411
Cariprazine		2-4 days, DDCAR 1-3 weeks	**CYP3A4,** CYP2D6	Desmethyl cariprazine (DCAR), Didesmethyl cariprazine (DDCAR)
Clozapine	12-81	11-105 hr	**CYP1A2, CYPD6, CYP3A4**	Desmethylclozapine
Iloperidone	96	18-33 hr	**CYP2D6, CYP3A4**	P88
Lumateperone	4.4	13-21 hr	**CYP3A4,** CYP1A2, CYP2C8, Aldoketoreductase 1C1, UGT1A1, UGT1A4, UGT 2B15	IC200131, IC200161, IC200565
Lurasidone	10-20	18 hr	**CYP3A4,** CYP1A2	ID-14233 and ID-14326
Olanzapine	80	20-70 hr	CYP1A2, CYP3A4, FMO3	*N*-Glucuronide; 2-OH-methyl; 4-*N*-oxide
Paliperidone ER	28	23 hr	Renal unchanged (59%) CYP3A4 and multiple pathways	None known
Quetiapine	9 ± 4	6.88 hr	**CYP3A4**, CYP3A5	N-desalkylquetiapine
Quetiapine XR		7 hr	**CYP3A4**, CYP3A5	N-desalkylquetiapine
Risperidone	68	3-24 hr	**CYP2D6**, CYP3A4	9-OH-risperidone
Ziprasidone	59	4-10 hr	Aldehyde oxidase, CYP3A4, CYP1A2	None

UGT, UDP glucuronosyltransferases genes; FMO3, flavin containing monooxygenase 3 gene; SL, sublingual.

[a] **Bold** print indicates major pathway.

Data from References 27-29, 60, 63-66, and 33,67.

Asenapine is unique in that it has less than 2% bioavailability after oral administration, but has a bioavailability of approximately 35% sublingually—the FDA-approved route of administration. Eating and drinking within 10 minutes after sublingual administration will reduce bioavailability, and bioavailability decreases with single doses above 10 mg.[28,66]

Most antipsychotics have long elimination half-lives, generally 24 hours or more, with the exception of quetiapine and ziprasidone, which have short half-lives.[63,66] Among the SGAs, only clozapine has an established therapeutic serum concentration, with efficacy being associated with a clozapine plasma concentration greater than 350 ng/mL (mcg/L; 1.07 μmol/L).[63] Whether a potential maximum therapeutic clozapine serum concentration exists is unknown. Clozapine serum concentration should be obtained before exceeding 600 mg daily, in patients who develop unusual or severe adverse medication reactions, in patients who are taking concomitant medications that can cause medication interactions, in patients who have age or pathophysiologic changes suggesting a change in pharmacokinetics, or for assessment of patient adherence.[63,66]

Adverse Medication Reactions

⑤ Table 87-7 presents the relative risk of common categories of antipsychotic adverse medication reactions, which are discussed below with respect to organ system affected. A general approach to monitoring and assessing adverse medication reactions requires prospective monitoring by clinicians, preferably using a thorough review of systems approach. Patient-oriented self-rated scales can be helpful, as many patients with schizophrenia do not readily endorse adverse medication reactions.

TABLE 87-7

Relative Incidence of Adverse Medication Reactions from Commonly Used Antipsychotics[a,b]

	Sedation	EPS	Anticholinergic	Orthostasis	Weight Gain	Prolactin
Aripiprazole	+	+[c]	+	+	+	±

EPS, extrapyramidal side effects—includes dystonias, parkinsonism, akathisia, and tardive dyskinesia.

Relative side effect risk: ±, negligible; +, low; ++, moderate; +++, moderately high; ++++, high.

[a] Adverse medication reactions shown are relative risk based on doses within the recommended therapeutic range.

[b] Individual patient risk varies depending on patient-specific factors.

[c] Primarily akathisia

As mentioned previously, adverse medication reactions are one of the primary predictors of patient nonadherence. With the variety of antipsychotics available, using an alternative should be considered to improve patient outcomes in those who endorse poorly tolerated adverse medication reactions. As we learn more about relative risks (eg, metabolic, QTc prolongation, and EPS), it will be necessary to regularly reconsider which antipsychotics should be considered first-line treatment alternatives.

Endocrine System

Within the hypothalamic tuberoinfundibular tract, DA blockade results in increased prolactin levels with hyperprolactinemia occurring in up to 71% of patients diagnosed with schizophrenia and treated with antipsychotics.[68] While US-based studies show no sex difference in the incidence of antipsychotic-induced hyperprolactinemia, UK-based studies suggest females are twice as likely to experience antipsychotic-induced hyperprolactinemia than males (52% vs 26%, respectively).[68,69] The major symptoms associated with hyperprolactinemia are gynecomastia, galactorrhea, menstrual irregularities, infertility, and sexual dysfunction. Although the clinical significance is unclear, chronic hyperprolactinemia has been associated with decreased bone mineral density, which may put patients at higher risk of osteoporosis.[70] Tolerance does not appear to develop to antipsychotic-induced hyperprolactinemia.[71] In general, FGAs are associated with higher rates of hyperprolactinemia than SGAs, the exceptions being risperidone and paliperidone which have reported rates exceeding 70%.[68,69,71] As they have poor penetration of the blood-brain barrier, their greater presence at D_2 receptors in the pituitary gland may be contributing to this adverse effect.[68,69,71] On the other hand, a D_2 partial agonist, aripiprazole is more prolactin sparing and other newer antipsychotics including asenapine, iloperidone, lurasidone, brexpiprazole, cariprazine, and lumateprone have not been shown to induce clinically meaningful changes in prolactin levels.[27,28,30,68,72,73]

If a patient experiences symptomatic hyperprolactinemia, switching to an agent that has minimal sustained effect on prolactin is a reasonable treatment option, as is attempting to lower the antipsychotic dose. However, both interventions run the risk of relapse. Augmentation with aripiprazole 5 to 30 mg daily may help reduce risperidone-induced hyperprolactinemia.[74] However, there have also been case series reporting symptom exacerbation with the addition of aripiprazole and, in general, antipsychotic polypharmacy is discouraged.[68] Dopamine agonists, bromocriptine, cabergoline, and pramipexole have been shown to decrease prolactin, but this approach is not recommended due to the lack of controlled trials, as well as reports of psychosis exacerbation.[68] For females with schizophrenia who suffer from amenorrhea due to antipsychotic-induced hyperprolactinemia, metformin 750 to 1,500 mg/day has been shown to restore menstrual function, with associated reduction in prolactin level.[75] While this is a potentially appealing intervention, especially in patients who are gaining weight and at risk for Type 2 diabetes mellitus (T2DM), additional evidence is needed before recommending metformin as a first-line intervention for females with antipsychotic-induced hyperprolactinemia.[75]

Weight gain is frequently reported in both adults and children receiving antipsychotics,[76,77] and is often seen within the first 12 weeks of antipsychotic initiation, with the rate of weight gain decreasing over time.[76,77] The risk of cardiovascular-related mortality is higher in individuals with schizophrenia,[78] and this is further aggravated by medication-related weight gain and the high prevalence of smoking. Additionally, obesity is a risk factor for diabetes mellitus.[78,79] Weight gain during treatment is concerning for patients and a reason for poor medication adherence.[55] Clozapine and olanzapine have the highest rates of antipsychotic-induced weight gain (AIWG), with olanzapine being the most studied and likely producing the highest risk. Mid-risk antipsychotics include asenapine, iloperidone, paliperidone, quetiapine, and risperidone. Aripiprazole, lurasidone, and ziprasidone are associated with the lowest risk of AIWG.[28,30,72,76] Newer agents, brexpiprazole, cariprazine and lumateperone, also appear to have low risk of AIWG, similar to aripiprazole.[31,33,73]

Although the exact mechanism for AWIG uncertain, it has been associated with antihistaminic effects, antimuscarinic effects, adrenaline alpha-1, and blockade of 5-HT$_{2C}$ receptors.[77] However, dietary factors and activity levels can play a significant role in this population, as well as nourishment after a period of poor self-care. The risk of weight gain may be greater in patients with their first psychotic episode and those who are underweight at baseline.

Several different genetic variations have been associated with predisposition for AIWG. The 5-HT$_{2c}$ gene and its relationship to AIWG is the most extensively studied polymorphism.[64,80] A meta-analysis of all genetic studies looking at the C–759T promoter region polymorphism of the *5-HT$_{2C}$* receptor gene confirmed the relationship with AIWG. While the C allele is the major allele in the population, the meta-analysis found that T allele is protective against AIWG.[80] In this same meta-analysis, polymorphisms of dopamine receptor D$_2$ (*D2*), alpha-2 adrenergic receptor (α_2), and melanocortin-4 receptor (*MC4R*) genes were also found to be associated with AIWG. Insulin-induced gene 2 (*INSIG2*) and Guanine Nucleotide Binding Protein (*GNB3*) had smaller effect sizes, but were also found to be associated with AIWG. Polymorphisms in leptin and leptin receptor genes, methylenetetrahydrofolate reductase (*MTHFR*), and brain-derived neurotrophic factor (*BDNF*) gene have been genetic targets; however, results are inconsistent regarding a potential relationship between these polymorphisms and AIWG.[64,80,81] In general, AIWG is most likely polygenic and impacted by environmental factors.

The combination of olanzapine and samidorphan was FDA approved for use in schizophrenia and bipolar disorder in May 2021. The addition of samidorphan, a functional opioid antagonist, to olanzapine is a novel approach to attenuate olanzapine-induced weight gain. In a 24-week Phase 3 trial, the olanzapine/samidorphan combination resulted in significantly less weight gain compared to olanzapine monotherapy, with the mean increase in weight of 3.18 kg (7.01 lb) and 5.08 kg (11.2 lb), respectively.[82] Additionally, significantly fewer subjects in the combination group had >7% weight gain as compared to olanzapine monotherapy (27.5% vs 42.7%, respectively). Unfortunately, the olanzapine/samidorphan combination did not result in any metabolic benefit when compared to olanzapine monotherapy.[82]

Several other approaches have been recommended to address weight gain. Switching the antipsychotic to another agent with less weight gain liability is one choice, and an American Diabetes Association consensus task force recommends consideration of a change in antipsychotic if a patient gains more than 5% of baseline body weight after starting the medication.[83] Metformin is effective in treating AIWG with a meta-analysis indicating an average of a 3.17 kg (6.99 lb) weight loss compared with placebo.[84] Dietary restriction, exercise, and behavior modification programs are reported to be successful. Both the Reducing Weight and Diabetes Risk in an Underserved Population (STRIDE) and the Randomized Trial of Achieving Healthy Lifestyles in Psychiatric Rehabilitation (ACHIEVE) clinical trials showed behavioral weight loss interventions resulted in significant weight loss in patients with mental illness receiving antipsychotics. The STRIDE study also showed reductions in fasting glucose over 6- and 12-month periods using such interventions.[80,85,86]

The Improving Metabolic Parameters in Antipsychotic Child Treatment (IMPACT) trial is the only randomized trial to compare different strategies to address overweight/obese youth who had experienced significant weight gain on antipsychotics.[87] All groups received health lifestyle education and were randomized to either the addition of metformin, a switch to aripiprazole, or continued their baseline antipsychotic. In this 24-week trial, the additional of metformin or a switch to aripiprazole resulted in a decrease in BMI z-score where continued antipsychotic resulted in an increase.[87]

Patients with schizophrenia have a twofold higher prevalence of T2DM compared with the general population.[78] While the illness itself contributes to elevated risk, antipsychotics are a major contributing factor, with individuals exposed to antipsychotics having higher rates of T2DM than those unexposed.[78,79] The exact mechanism by which antipsychotics elevate the risk of T2DM is unknown. While weight gain seen with antipsychotics can lead to insulin resistance and elevated risk of T2DM, a systematic review of antipsychotic-associated diabetic ketoacidosis (DKA) found that weight gain was only associated with roughly half of the included cases, and DKA was often the first indicator of a diabetes diagnosis. The SGAs can rapidly and directly influence glucose metabolism independent of AIWG and adiposity.[88] Antipsychotics also may directly cause T2DM through increased insulin resistance or impaired β-cell function or a combination of the two.[79] The greatest increase in glucose impairment typically occurs during the first 14 weeks of treatment,[85] and for clozapine, olanzapine, quetiapine, and risperidone nearly 60% of new-onset diabetes occurred within the first 6 months of treatment initiation.[83,85]

The FDA-approved product labeling for all SGAs reflects the increased risk of diabetes mellitus in patients taking these medications, but risk varies based on the antipsychotic. Clozapine and olanzapine have the highest risk of new-onset diabetes followed by quetiapine and risperidone, while the risk appears lowest with ziprasidone and aripiprazole.[83,85] Although inadequate data are available for asenapine, iloperidone, lurasidone, brexpiprazole, cariprazine, and lumateperone, their risk also appears low.[33,89] Olanzapine is not recommended as a first-line antipsychotic option due to its metabolic risks[14,22,23]; therefore, designing care models and standards for managing diabetes in patients with schizophrenia is important in addressing this major health problem.

Cardiovascular System

Orthostatic Hypotension

Orthostatic hypotension, thought to be caused by α-adrenergic blockade, is a common adverse reaction of antipsychotics.[90] Clozapine and quetiapine had the highest incidence of orthostatic hypotension in the CATIE study, and iloperidone appears to have the highest risk among newer SGAs.[90] Orthostatic hypotension can occur in any patient, but patients with diabetes and pre-existing cardiovascular disease and older adults are particularly predisposed. Other risk factors may include dehydration, presence of alcohol associated neuropathy and antipsychotic combination treatment.[90,91] Patients should be advised to avoid sudden positional changes to allow for adaptation. Tolerance to orthostatic hypotension may occur within 2 to 3 months. If not, lower doses or a change to an antipsychotic with less α-blockade can be attempted. Fluid resuscitation or increasing salt intake may also help minimize orthostatic blood pressure changes.[90,91]

Electrocardiographic Changes

The electrocardiographic (ECG) changes seen with antipsychotics include increased heart rate (through sinus tachycardia from anticholinergic effects, or reflex tachycardia from α-adrenergic blockade), flattened T waves, ST segment depression, and prolongation of QT and PR intervals. The most clinically important of these potential changes is prolongation of the QTc interval, which has been associated with ventricular arrhythmias, including torsade de pointes syndrome. This is thought to occur as a result of blockade of the cardiac delayed potassium rectifier channel as well as impairment in autonomic function.[89,91] Among the antipsychotics, thioridazine is most likely to cause these changes and has been shown to prolong the QTc an average of about 30 msec, which is over 20 msec longer than haloperidol, risperidone, olanzapine, or quetiapine, and 15 msec longer than ziprasidone.[92] Thioridazine's effect on QTc prolongation is dose related, and has led to a boxed warning in the FDA-approved product labeling. A comprehensive review was not able to stratify the degree of QTc prolongation of nine different SGAs.[93] Iloperidone, however, is subject to pharmacogenomic differences in metabolism, and there may be an increased risk of QTc prolongation in CYP2D6 poor metabolizers.[27] High IV doses of haloperidol elevate the risk for QTc prolongation, resulting in a boxed warning in the FDA-approved labeling.[94] Although the precise point at which QTc prolongation becomes clinically dangerous is unclear, the risk for arrhythmia escalates when the QTc interval exceeds 500 msec, or is 60 msec above the baseline QTc.[93,94] Accordingly, it has been recommended to discontinue a medication associated with QTc prolongation if the interval consistently exceeds 500 msec. QTc intervals greater than or equal to 450 msec and/or a 30 msec increase in QTc interval from baseline may be predictors of a medication's risk to cause torsades.[93]

While QTc prolongation may predict torsade de pointes, it rarely happens in the absence of other risks factors, including patients greater than 60 years, female gender, those with preexisting cardiac or cerebrovascular disease (including bradycardia, second- or third-degree AV block, and congenital long QTc syndrome), hepatic impairment, hypokalemia, hypomagnesemia, concomitant medications that prolong the QTc interval, metabolic inhibition by another medication, or preexisting QTc prolongation.[93,94] For patients over the age of 50 years of age, a pretreatment ECG is recommended, as are baseline serum potassium and magnesium levels.

Myocarditis and Cardiomyopathy

Myocarditis is an infrequent and dose independent adverse effect that is most likely to occur with clozapine, but has been reported with quetiapine,[90] and possibly with olanzapine.[95] Eighty-seven percent of clozapine-induced myocarditis cases occur within the first 4 weeks of treatment, but cases as late as 22 weeks have been reported.[89,96] Symptoms of clozapine-induced myocarditis can be nonspecific and include: flu-like symptoms (eg, fever, myalgias), respiratory (eg, dyspnea, cough, orthopnea), and cardiac (persistent tachycardia, chest pain, syncope) symptoms. Myocarditis is considered a life-threatening event and therefore early detection is essential. While the incidence of clozapine-induced myocarditis may be as high as 3%, and the mortality rate upwards of 10% to 30%, there are no mandatory monitoring parameters.[96] Recommended laboratory monitoring has been proposed with baseline and weekly monitoring of C-Reactive Protein (CRP) for the first 4 weeks, while troponin (I or T) and B-type natriuretic peptide monitoring has also been suggested. A baseline echocardiogram (ECHO) is recommended and repeated if myocarditis is suspected. Both CRP elevations above 100 mg/L and troponin greater than two times the upper limit of normal have been shown to be highly sensitive in detecting clozapine-induced myocarditis. Clozapine rechallenge after the occurrence of myocarditis is debated, and only a few cases have been reported. The decision to rechallenge should only be made in patients where the clinical value greatly outweighs the potential risk, and only after full resolution of the myocarditis and no signs of permanent cardiac damage. A rechallenge should be conducted in a hospital where close monitoring can occur, as myocarditis recurrence during rechallenge has been reported.[96]

Cardiomyopathy, a potentially life-threatening adverse effect, can also be seen with clozapine, which typically presents later during treatment than myocarditis, with an average time of onset of 14 months.[96,97] The current incidence of cardiomyopathy is estimated to be 0.02% to 0.1%, but this adverse effect may be under-reported,[97] as shortness of breath, palpitations, and fatigue are the most frequently reported symptoms. The diagnosis of cardiomyopathy is typically made with an ECHO with a reduction in ejection fraction (EF) being the most consistent finding. For patients with an EF less than 25%, lower recovery and higher mortality rates have been seen, whereas those with an EF greater than 40% typically fully recover.[97] In suspected cases of clozapine-induced cardiomyopathy, clozapine should be discontinued, and a rechallenge is not recommended.[98]

Sudden Cardiac Death

The risk of sudden cardiac death (SCD) with use of FGAs and SGAs is reported to be twice that of nonusers, with risk increasing with escalated dose.[89,90] Fifteen cases of SCD may occur per 10,000 years of antipsychotic exposure.[89,90] There is insufficient evidence to confer a greater risk with one class of antipsychotics over another.[89,90] A case-crossover study involving over 17,000 patients showed that antipsychotic use was associated with a 1.53-fold increase in ventricular arrhythmia or SCD. The magnitude of effect was greatest among patients who received antipsychotics for a short term (less than 28 days).[99] Nonetheless, prospectively designed studies are needed to confirm dose-dependency with antipsychotic-associated cardiovascular sudden death, and whether risk is different among antipsychotics.

Lipid Changes

Treatment with at least some SGAs and phenothiazines is associated with elevated serum triglycerides and cholesterol. Among the SGAs, olanzapine, clozapine, and quetiapine have the highest risk for dyslipidemia, with elevations in serum triglycerides being the most frequently reported abnormality.[28,30] Increased appetite and subsequent weight increase can negatively affect lipids. Independent of weight gain, antipsychotic effects on apolipoprotein B, lipoprotein oxidation, and elevations in sterol regulatory element binding protein-controlled gene expression are among possible mechanisms by which lipid changes may occur with antipsychotics.[100] As previously discussed, olanzapine is associated with greater and significant adverse effects on metabolic parameters, including lipids, blood glucose, and body weight as compared with other antipsychotics in the CATIE trial.[17]

The occurrence of weight gain, diabetes, and lipid abnormalities during antipsychotic therapy is consistent with the development of metabolic syndrome, and cohorts of patients with schizophrenia have shown elevated prevalence of metabolic syndrome as compared with general population cohorts. Prevalence rates of metabolic syndrome in US populations treated with antipsychotics range from 28% to 60%, with 40.9% reported in the prospectively designed CATIE trial.[101]

Metabolic syndrome consists of raised triglycerides (greater than or equal to 150 mg/dL [1.70 mmol/L]), low HDL cholesterol (less than or equal to 40 mg/dL [1.03 mmol/L] for males, less than or equal to 50 mg/dL [1.29 mmol/L] for females), elevated fasting glucose (greater than or equal to 100 mg/dL [5.6 mmol/L]), blood pressure elevation (greater than or equal to 130/85 mm Hg), and weight gain (abdominal circumference greater than 102 cm [40 in.] for males, greater than 89 cm [35 in.] in females).[102] A diagnosis of metabolic syndrome can be made in individuals who meet at least three of these criteria. Therefore, these abnormalities dictate an important role for general health screening and monitoring in patients with schizophrenia, and prompt intervention when such abnormalities occur. The propensity of individual antipsychotics to produce metabolic disturbances should be considered in the context of individual patient risk factors at the time of medication selection.

Thromboembolism

Compared to the general population, the risk of venous thromboembolism (VTE) is twofold higher in individuals with schizophrenia. Sedentary lifestyle, smoking, and metabolic syndrome are all potential explanations for the higher incidence. Increased rates have also been reported in stuporous catatonia and prolonged physical restraints. Additionally, both FGAs and SGAs have been associated with elevating the risk of VTE. The risk may be highest within the first 30 days of antipsychotic exposure and with higher doses. Although the mechanism for increased VTE risk is unknown, increased sedative adverse medication reactions, metabolic effects, antipsychotic effect on platelet aggregation, and hyperprolactinemia indirectly increasing venous stasis have been proposed.[103] The QThrombosis (https://qthrombosis.org/) is a validated VTE risk calculator that includes antipsychotics in the risk assessment model.[104] This tool may be helpful in identifying patients at elevated risk for VTE and can easily be implemented in clinic practice.

Anticholinergic Effects

Patients receiving antipsychotics or antipsychotics in combination with anticholinergics can experience anticholinergic adverse reactions (eg, dry mouth, constipation, tachycardia, blurred vision, inhibition or impairment of ejaculation, urinary retention, or impaired memory). These adverse medication reactions are particularly seen with low-potency FGAs, and in older adult patients who are especially sensitive to these effects. Of the SGAs, clozapine and olanzapine have moderately high rates of anticholinergic effects. Constipation, caused by slowed peristaltic movement and decreased intestinal fluid content, should be closely monitored and treated, especially in older adults. Paralytic ileus and necrotizing enterocolitis can also occur.[89,90]

Central Nervous System

Extrapyramidal System

Extrapyramidal symptoms (EPS) is an umbrella term used to describe antipsychotic-induced movement symptoms due to excess dopamine blockade in the nigrostriatal pathway. These symptoms include: dystonia, akathisia, parkinsonism, and tardive dyskinesia, which are explained in detail below.

Dystonia

Dystonia is a state of abnormal tonicity, sometimes described simplistically as a severe "muscle spasm.[105] More accurately, dystonias are prolonged tonic contractions, with a rapid onset, usually within 24 to 96 hours of initiating or increasing the dose of an antipsychotic.[106] Types of dystonic reactions include trismus, glossospasm, tongue protrusion, pharyngeal–laryngeal spasms, blepharospasm, oculogyric crisis, torticollis, and retrocollis, but can occur with any skeletal muscle group. They can be life threatening, as in the case of pharyngeal–laryngeal dystonias, and can contribute significantly to patient medication nonadherence. Dystonic reactions occur primarily with high potency FGAs and are greatly reduced with SGAs. Risk factors for dystonia include younger patients, male sex, the use of high-potency agents, rapid titration and high dosage. The overall incidence from the 1960s to the mid-1970s ranged from 2.3% to 10%, but as higher-potency traditional antipsychotics became more widely used, the rate increased to as high as 64%.

Intramuscular or IV anticholinergics (Table 87-8) are the treatment of choice for dystonias, with benzodiazepines being a second-line option.[106] Benztropine 2 mg or diphenhydramine 50 mg can be given IM or IV, whereas diazepam 5 to 10 mg by slow IV push or lorazepam 1 to 2 mg intramuscularly are treatment alternatives. Relief from the dystonia is typically seen within 15 to 20 minutes of an IM injection or within 5 minutes of IV administration. The antipsychotic can be continued, with concomitant short-term use of an oral anticholinergic, which is then subsequently tapered and stopped. In general, prophylactic anticholinergic medications are not recommended routinely. However, prophylaxis is reasonable when using high-potency FGAs (eg, haloperidol or fluphenazine) in young males and in patients with a history of dystonia.[105] Dystonias can also be minimized by the use of lower initial FGA doses or the use of SGAs. Anticholinergics are good choices for prophylaxis, whereas amantadine has not been proven effective for this purpose.

TABLE 87-8

Agents Used to Treat Extrapyramidal Symptoms

Generic Name	Equivalent Dose (mg)	Daily Dosage Range (mg)
Antimuscarinic		
Benztropine[a]	1	1-8[b]
Biperiden[a]	2	2-8
Trihexyphenidyl	2	2-15
Antihistamine		
Diphenhydramine[a]	50	50-400
Dopamine Agonist		
Amantadine	NA	100-400
Benzodiazepine		
Lorazepam[a]	NA	1-8
Diazepam	NA	2-20
Clonazepam	NA	2-8
β-Blocker		
Propranolol	NA	20-160

NA, Not applicable.

[a] Injectable dosage form can be given intramuscularly for relief of acute dystonia.

[b] In treatment-refractory cases, dosage can be titrated to 12 mg/day with careful monitoring; nonlinear pharmacokinetics have been reported.

Akathisia

Akathisia is defined as the inability to sit still and having functional motor restlessness. The most accurate diagnosis is made by combining subjective patient reports with objective observations (pacing, shifting, shuffling, or tapping feet). Subjectively, patients may describe a feeling of inner restlessness or disquiet or a compulsion to move or remain in constant motion that provides some relief. Akathisia occurs in 20% to 40% of patients treated with high-potency FGAs[105,107] and is frequently accompanied by dysphoria. In severe cases, akathisia may be mistaken for aggression and if left untreated, has been linked to insomnia, increased suicidality, and development of tardive dyskinesia.[107]

Akathisia generally appears early in antipsychotic treatment, but can be chronic if not appropriately addressed.[107] Risk of akathisia is greater when the antipsychotic dose is increased rapidly or multiple antipsychotics are used, as well as in antipsychotic naïve individuals.[107] Traditionally, a reduction in antipsychotic dosage has been considered the best intervention; however, this might not be a realistic goal in a patient with acute psychosis. A logical alternative is to switch to an antipsychotic with a lower risk of akathisia, or an antipsychotic the patient previously tolerated. Akathisia can occasionally occur with SGAs, particularly aripiprazole, cariprazine, lurasidone, or risperidone. Iloperidone, quetiapine and clozapine appear to have the lowest risk of producing akathisia.[72,107]

Unlike acute dystonias, akathisia responds poorly to anticholinergics;[107] therefore, benzodiazepines have been used for treatment of akathisia, but the high prevalence of co-occurring substance use disorders in schizophrenia discourages their use.[107] The β-blockers (eg, propranolol in doses up to 160 mg daily) are effective and have the most evidence.[105,107] Additionally, 5-HT_2 receptor antagonists may be protective against akathisia and may be used for its management. Examples of such agents include mirtazapine, trazodone, and cyproheptadine, with mirtazapine having the most data to support its use.[105,107]

Parkinson Symptoms

Antipsychotic-induced parkinson symptoms resembles idiopathic Parkinson disease with symptom onset typically within 1 to 2 weeks after antipsychotic initiation or a dose increase. For some it may be delayed with 50% to 75% of cases occurring within a month and 90% within 3 months.[105,106] A patient with antipsychotic-induced parkinson symptoms can present with any of four cardinal symptoms: (a) akinesia, bradykinesia, or decreased motor activity including difficulty initiating movement, as well as extreme slowness, mask-like facial expression, micrographia, slowed speech, and decreased arm swing; (b) tremor that is predominant at rest and decreases with movement, and known as the pill-rolling type, usually involves the fingers and hands, although tremors can also be seen in the arms, legs, neck, head, and chin; (c) cogwheel rigidity, seen as the patient's limbs yielding in jerky, ratchet-like fashion when passively moved by the examiner; and (d) postural abnormalities and instability manifested as stooped posture, difficulty in maintaining stability when changing body position, and a gait that ranges from slow and shuffling to festinating. Fatigue and weakness can be noted, as well as oral abnormalities including dysphagia, dysarthria, and abnormal palmomental and glabellar reflexes. The overall incidence of FGA-induced parkinson symptoms ranges from 15.4% to 36%, depending on the medication and dose, and akinesia alone can be seen in 59% of patients on high-potency FGAs. The risk of parkinson symptoms with SGAs is low. A secondary data analysis from the CATIE study did not find marked differences in rates of EPS between perphenazine and SGAs, suggesting that a less potent FGA at modest doses may present a similar risk of parkinson symptoms as SGAs.[108] Other risk factors for the development of parkinson symptoms include increasing age and possibly female sex.

The efficacy of anticholinergic medications in treating symptoms of antipsychotic-induced parkinson symptoms is well established,[105,106] although diphenhydramine produces more sedation than the other agents. Table 87-7 outlines the dosing of these medications. Symptoms typically begin to resolve within 3 to 4 days after initiation of treatment, but a minimum of at least 2 weeks of treatment is normally required for full response. Amantadine may be as efficacious for parkinson symptoms as anticholinergics, but with significantly less impact on cognition.[105,106] Prophylactic use of these agents against parkinson symptoms is less convincing compared with dystonias, and is unnecessary when using SGAs.[105,106] The long-term treatment of parkinson symptoms with antiparkinson medication is somewhat controversial. An attempt should be made to taper and discontinue these agents in 6 weeks to 3 months after symptom resolution. If symptoms reappear, then switching to an SGA should be considered. Quetiapine, aripiprazole, brexpiprazole, iloperidone, asenapine, lumateperone, and clozapine are reasonable alternatives in a patient experiencing EPS with other SGAs.[33,72,109]

Tardive Dyskinesia

Tardive dyskinesia (TD) is a syndrome characterized by abnormal involuntary hyperkinetic movements occurring late in onset in relation to initiation of antipsychotic therapy. The classic description of tardive dyskinesia is an insidious onset of oral or orofacial movements often associated with lip smacking or tongue thrusting as the disorder progresses, which can interfere with the patient's ability to chew, speak, or swallow. Other facial movements include frequent blinking, brow arching, grimacing, and upward deviation of the eyes. Involvement of the extremities sometimes occurs, and may involve any skeletal muscle group. Orofacial movements are more common in older patients, whereas the truncal axial movements are classically reported in young adults. Movements can worsen with stress, decrease with sedation, and disappear during sleep. Concentration on motor tasks or attempts to suppress the movements can increase them.[110]

Early signs of tardive dyskinesia can be reversible but if allowed to persist, can become irreversible, even with medication discontinuation. The exact time point in which TD becomes irreversible is unknown, which underscores the importance of early detection.[106] When the antipsychotic dose is decreased or tapered and discontinued, worsening of abnormal movements may occur, followed by possible slow improvement after months or years if the patient remains on lower doses or discontinues treatment. Younger age correlates with a greater chance of reversing TD.[106] No standardized diagnostic criteria for tardive dyskinesia are available. Abnormal involuntary movements can be detected early through physical assessment and the use of rating scales. Available rating scales include the Abnormal Involuntary Movement Scale (AIMS) and the Dyskinesia Identification System: Condensed User Scale (DISCUS).[109] Neither scale is diagnostic (see Chapter e81).

One of the greatest risk factors for TD is older age, with patients over 65 having a two-to-fivefold higher incidence of TD than younger adults.[111] Other possible risk factors include history of acute EPS, poor antipsychotic medication response, diagnosis of organic mental disorder, diabetes mellitus, mood disorders, female sex, use of anticholinergics, current and cumulative antipsychotic doses, and duration of antipsychotic exposure.[110] Additionally, genetic variation within CYP2D6, vesicular monoamine transporter-2 (VMAT2) gene, and D_2 receptor gene have been suggested as being associated with increased risk.[112] A systematic review of 12 studies lasting 1 year or more found the overall risk of TD with SGAs to be approximately 2.9% per year in adults under 65 years of age as compared with 7.7% for FGAs.[113] These results were confirmed with a meta-analysis which indicated that olanzapine and aripiprazole may have a small advantage over other non-clozapine SGAs.[114] Tardive dyskinesia is not always permanent, with spontaneous remission of symptoms observed in 25% of patients after 5 years of continued treatment;[24] however, overall morbidity and mortality are greater in tardive dyskinesia patients.

Prevention of TD is important, as treatment of the movements once they occur is difficult. One of the more compelling arguments for the first-line use of SGAs is their lower risk of TD.[24] Therefore, regular neurologic examinations (AIMS or other scales) should be performed at baseline, and APA guidelines recommend TD monitoring at least every 6 months for those at high risk and every 12 months for all others.[22] At the first sign of TD, the need for continuing antipsychotic treatment should be assessed, and if the patient is taking an FGA and continuing treatment is indicated, the medication should be switched to an SGA.

The VMAT2 inhibitors deutetrabenazine and valbenazine are FDA-approved medications for the treatment of TD. Both are considered first-line interventions, as they produced clinically significant decreases in AIMS scores in both short- and long-term trials.[115] However, when valbenazine treatment is discontinued, TD symptoms can rapidly return toward pretreatment levels within 4 weeks after discontinuation.[116]

Deutetrabenzine should be initiated at 6 mg twice daily with food, with weekly dose increases of 6 mg up to a maximum dose of 48 mg per day. It is primarily metabolized via CYP2D6 and a maximum daily dose of 36 mg is recommended with concomitant strong CYP2D6 inhibitors or in CYP2D6 poor metabolizers.[103] It is contraindicated in individuals with severe hepatic impairment or those taking a monoamine oxidase inhibitor. Valbenazine is initiated at 40 mg once daily and increased to 80 mg after 1 week. This medication is not recommended for use in combination with strong CYP3A4 inducers, and a maximum daily dose of 40 mg is recommended when used with CYP3A4 strong inhibitors. Use in individuals with severe renal impairment is not recommended. Labeling for both deutetrabenzine and valbenazine includes warnings about suicidality, depression, and QTc prolongation.[115,116]

Numerous other medications have been used to treat tardive dyskinesia. In two controlled trials lasting 22 to 52 weeks, clozapine decreased abnormal involuntary movement,[24] therefore switching to clozapine has been recommended as a treatment for moderate-to-severe TD.[14,22-24] A 2013 guideline developed by the American Academy of Neurology (AAN) recommended short-term treatment of TD with either clonazepam (up to 4.5 mg daily) or ginkgo biloba extract 240 mg daily based upon randomized clinical trial data. However, long-term treatment data are lacking.[117] The AAN guideline was developed before the availability of the two VMAT2 inhibitors. However, in patients who do not have access to these agents, or do not tolerate or respond with their use, clonazepam or ginkgo biloba can be considered.[115]

Seizures

An increased risk of medication-induced seizures can occur in patients receiving antipsychotics as these agents decrease the seizure threshold. However, this risk is greater if the following predisposing factors are present: preexisting seizure disorder, history of medication-induced seizure, abnormal electroencephalogram (EEG), and preexisting CNS pathology or head trauma. Seizures are more closely associated with high plasma concentrations, rapid dosage titration, and treatment initiation. The exact mechanism is unknown, but involvement of D_2 and D_S receptors has been proposed.[90] When an isolated seizure occurs, a dosage reduction of the antipsychotic is first recommended, and routine prophylactic use of antiseizure medication is not recommended. Although spontaneously occurring seizures have been reported with most antipsychotics, the highest potential risk for an antipsychotic-related seizure is with clozapine or chlorpromazine. If a change in antipsychotic therapy is required because of a medication-induced seizure, aripiprazole, risperidone, thioridazine, haloperidol, pimozide, trifluoperazine, and fluphenazine are associated with the lowest potential.[90]

Thermoregulation

Poikilothermia, the body temperature adjusting to the ambient temperature, can be a serious adverse reaction in temperature extremes.[118] Hyperpyrexia can be a danger in hot weather or during exercise. Additionally, inhibition of sweating, a result of anticholinergic properties impairing the peripheral mechanisms of heat dissipation can contribute to this problem, which in its severest form can lead to heat stroke. Hypothermia is a risk in cold temperatures, particularly in older adults. All patients receiving antipsychotics should be educated about these potential problems. Thermoregulatory problems are reportedly more common with the use of low-potency FGAs, but can occur with the more anticholinergic SGAs.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) occurs in <1% of patients and is reported with both FGAs and SGAs, with the highest incidence occurring with high-potency FGAs.[90] High antipsychotic doses, rapid parenteral administration, use of multiple antipsychotics, previous history of NMS, dehydration, physical restraints, and older age all increase the risk.[90] Symptoms are most likely to occur within the first week of antipsychotic initiation and develop rapidly over the course of 24 to 72 hours. The mortality rates associated with NMS is high at approximately 10%, with premorbid dehydration elevating the risk of mortality.

Possible mechanisms of NMS include disruption of the central thermoregulatory processes or excess production of heat secondary to skeletal muscle contractions, including the involvement of proinflammatory cytokines. Regardless of the mechanism, the differential diagnoses for NMS include: heat stroke, lethal catatonia, malignant hyperthermia, anticholinergic toxicity, and serotonin toxicity. The cardinal signs and symptoms of NMS are body temperature exceeding 38°C (100.4°F) on at least two occasions, mental status changes, autonomic instability (tachycardia, blood pressure, diaphoresis, tachypnea, or urinary or fecal incontinence), and rigidity.[119] Laboratory evaluation, although nonspecific, frequently shows leukocytosis with or without a left shift, and increases in creatine kinase, aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and myoglobinuria.[118,119] Importantly, NMS treatment should begin with antipsychotic discontinuation and supportive care (eg, IV fluid hydration and benzodiazepines). Dantrolene, bromocriptine, or amantadine may be useful in severe cases as all three agents have reports of reduced time to clinical improvement and reduction in mortality rates.[118]

Many patients with schizophrenia, despite having had NMS, will require future antipsychotic pharmacotherapy. The literature suggests that the risk of rechallenge is acceptable in most patients, provided that the patient is observed for an extended period of time (2 weeks or more is suggested) without antipsychotics, that there is careful monitoring, slow dose titration, and that the patient is maintained on the lowest possible dose.[118,119] A different antipsychotic, an SGA or a low-potency FGA, should be used for rechallenge following an episode of NMS.

Psychiatric Adverse Medication Reactions

Aripiprazole has been associated with impulse control disorders, including pathological gambling, uncontrolled sexual urges, uncontrolled spending, binge or compulsive eating and other intense urges. This led to an FDA safety announcement in 2016 and subsequent update to the warnings in the package labeling for all aripiprazole products.[120] Mechanistically the D_2 partial agonist activity and possible D_3 receptor activity seen with aripiprazole have been implicated as potential pathways for these reactions.[120] Clinicians are encouraged to monitor for changes in impulse control behaviors and reduce the dose or stop aripiprazole should urges develop or worsen.

Ophthalmologic Effects

Anticholinergic effects of antipsychotics or concomitant antiparkinson medications can exacerbate narrow-angle (angle-closure) glaucoma. Therefore, antipsychotics with low anticholinergic effects should be used in such individuals, and they should be appropriately monitored.[121]

Opaque deposits in the cornea and lens can occur with chronic phenothiazine treatment, with this adverse event occurring most frequently with chlorpromazine. Although visual acuity is not usually affected, periodic ophthalmologic examinations are frequently recommended in patients receiving long-term treatment with phenothiazines, as fully formed cataracts are possible.[121]

Because of cataract development and lenticular changes in animals, baseline and periodic eye examinations are recommended in quetiapine product labeling. However, effect of quetiapine on lens opacity was found to be no different than risperidone in a 2-year comparative trial.[122] Lastly, retinitis pigmentosa can result from use of thioridazine doses greater than 800 mg daily, due to melanin deposits that can result in permanent visual impairment or blindness.

Genitourinary System

Urinary hesitancy and retention, secondary to antipsychotic anticholinergic effects are reported with low-potency FGAs and with clozapine; those with benign prostatic hypertrophy are especially prone to this effect.[90] Reducing the antipsychotic dose or switching to an antipsychotic with less anticholinergic activity may help. Alternatively, bethanecol can be used to treat antipsychotic-induced urinary hesitancy and retention.

Urinary incontinence is thought to be caused by α-blockade, and among the SGAs, it appears to be particularly problematic with clozapine.[90] The incidence has been reported to be as high as 44%, and it can be persistent in 25% of patients. Female sex and previous urinary incontinence can be risk factors for developing incontinence.[90]

Although inadequately studied, multiple mechanisms are likely responsible for sexual dysfunction seen with antipsychotic use, including dopaminergic blockade, hyperprolactinemia, histaminergic blockade, anticholinergic effects, and α-adrenergic blockade. However, unmedicated individuals with schizophrenia also report decreased libido. Most, but not all, studies show a relationship between hyperprolactinemia and sexual dysfunction, including decreased libido, erectile dysfunction, difficulty achieving orgasm, and ejaculatory abnormalities. Risperidone and paliperidone produce at least as much sexual dysfunction as FGAs, while other SGAs, with weak effects on prolactin, produce less sexual dysfunction. Patients experiencing sexual dysfunction with FGAs or risperidone or paliperidone should be switched to an SGA with less effect on prolactin.[123]

Priapism, a sustained and painful erection that is unprovoked and persists for longer than an hour, is increasingly reported with antipsychotic medication use. This is believed to occur because of α_1-adrenergic receptor blockade, leading to intracavernosal blood stasis.[124] This can evolve into a urologic emergency, due to the ischemic nature of the priapism, and as such patients experiencing this adverse event require emergency treatment. If left untreated, priapism may lead to permanent impotence.

Hematologic System

Transient leukopenia can occur during initial treatment with antipsychotics; however, it typically does not progress to be clinically significant.[125] Agranulocytosis reportedly occurs in 0.01% of patients receiving FGAs, and more frequently with chlorpromazine and thioridazine. The three antipsychotics with the highest relative risk for neutropenia in rank order are clozapine, chlorpromazine, and olanzapine.[125] The onset is usually within the first 8 weeks of therapy. If the absolute neutrophil count (ANC) is less than 500/μL (0.5×10^9/L), the antipsychotic should be discontinued and the ANC monitored closely until it returns to normal and the patient monitored for the development of secondary infections. Agranulocytosis can initially manifest as a local infection, with sore throat, leukoplakia, erythema, and ulcerations of the pharynx. These symptoms in any patient receiving antipsychotics should signal the immediate need for an ANC. Additionally, isolated rare cases of thrombocytopenia and eosinophilia have been reported.

Agranulocytosis with clozapine has significantly inhibited use of this agent, and it is only available in the United States through the Clozapine REMS Program.[32] The risk of developing neutropenia or agranulocytosis with clozapine is approximately 3% and 0.8%, respectively,[124] and most cases occur between 6 weeks and 6 months. The baseline ANC must be at least 1,500/μL (1.5×10^9/L) to start clozapine, and weekly ANC monitoring for the first 6 months of therapy is mandated in the FDA-approved product labeling. After this time, if the patient's ANC remains greater than 1,500/μL (1.5×10^9/L), the labeling allows monitoring to be decreased to every 2 weeks for the next 6 months. After this, monitoring can be decreased to monthly if all ANCs remain greater than 1,500/μL (1.5×10^9/L). If at any time the ANC drops to less than 500/μL (0.5×10^9/L), clozapine must be discontinued and the ANC monitored daily until it is greater than 1,500/μL (1.5×10^9/L). The FDA-approved product labeling should be consulted for more detailed information regarding ANC monitoring, including monitoring for mild and moderate leukopenia and recommendations for patients with benign ethnic neutropenia.[32]

Dermatologic System

Allergic reactions are rare and usually occur within 8 weeks of initiating therapy, manifesting as maculopapular, erythematous, pruritic rashes that are evident on the face, neck, trunk, or extremities. Contact dermatitis, including the oral mucosa, has been reported in patients and medical personnel exposed to FGA liquid formulations. The risk of oral mucosal reactions can be decreased by mixing the FGA concentrate in a sufficient quantity of a nonacidic liquid and swallowing it quickly. Care should be taken in the handling and preparation of liquid FGAs. Ziprasidone's FDA-approved label contains a warning regarding the risk of a rare but fatal skin reaction called *Drug Reaction with Eosinophilia and Systemic Symptoms* (DRESS).[126]

Phenothiazines can absorb ultraviolet light, resulting in the formation of free radicals, which can have damaging effects on the skin. All antipsychotics can cause photosensitivity resulting in erythema and sunburn; therefore, exposure to sunlight should be limited, and patients should be educated about the use of a maximally blocking sunscreen, hats, protective clothing, and sunglasses.[125]

Blue-gray or purplish skin coloration in areas exposed to sunlight occurs in patients receiving higher doses of low-potency phenothiazines during long-term administration, especially with chlorpromazine. This adverse event commonly occurs with concurrent corneal or lens pigmentation.

Miscellaneous Adverse Effects

Clozapine-induced sialorrhea (drooling), which is typically prominent at night,[125] affects up to 54% of patients receiving clozapine. The mechanism behind this drooling is unclear; however, two theories exist. The first involves muscarinic receptor activity and clozapine's imbalanced binding affinity to this receptor. The other involves clozapine's α-antagonist activity at the salivary glands leaving unopposed beta-receptor stimulation and hence hyper-salivation.[125] Anticholinergics such as benztropine and atropine, and α-agonists such as clonidine have been used to treat clozapine-related sialorrhea.[127]

Use in Pregnancy and Lactation

The reproductive health of females with schizophrenia has historically received little attention from clinicians or researchers, partly due to reports of lower fertility rates in individuals with schizophrenia. However, with the introduction of more prolactin sparing SGAs (exceptions being risperidone and paliperidone), fertility rates in schizophrenia are increasing.[128] While data on the safety of antipsychotic medication use during pregnancy and lactation are limited, greater than 50% of individuals with schizophrenia who discontinue their medication will experience relapse.[129] Additionally, pregnant individuals with untreated schizophrenia are more likely to use alcohol, tobacco and other substances and are less likely to engage in prenatal care visits.[127] Therefore, these factors may put pregnant individuals and their offspring at greater risk, outweighing any potential risks associated with antipsychotic use.

The risk of teratogenesis with FGAs has not been sufficiently studied, and a specific pattern of teratogenicity has not been found.[130,131] The use of phenothiazines and low dose haloperidol to treat hyperemesis gravidarum provide additional reassurance that FGAs are not major teratogens.[132] Haloperidol is the best studied FGA with approximately 400 reported exposures.[127] With regard to labor and delivery complications, one small study found greater than a two-fold elevated risk of preterm birth in pregnant individuals with schizophrenia taking FGAs as compared with those not taking antipsychotics, but did not find an association between FGA exposure and low birth weight or small for gestational age.[133] A major limitation in interpreting this study are the confounding variables such as disease severity, concurrent substance use or other concurrent medications that were not addressed.

Data regarding the safety of SGAs in pregnancy are rapidly increasing but also limited. All SGAs cross the blood-placenta barrier, but to varying degrees. In one study sample, the highest rates of transfer were for olanzapine (72.1%), followed by haloperidol (65.5%) and risperidone (49.2%), with quetiapine being the lowest (24.1%).[134] Among the SGAs, safety data are most abundant for olanzapine, quetiapine, aripiprazole, and risperidone. As a class, SGAs are not thought to be major teratogens. Results from the largest database study to date (9,258 pregnant females with SGA exposure in the first trimester) suggest that the SGAs aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone collectively do not increase the risk of congenital malformations or cardiac malformation. This finding held true when evaluating each agent individually, except for a small, but statistically significant increase of congenital malformations with risperidone (RR, 1.26; 95% CI, 1.02-1.56).[135-138] A meta-analysis of 12 studies (which did not include the previous study) found a greater risk of congenital malformations with SGA exposure in early pregnancy, but no specific abnormality was identified. In this same study, an increased risk of preterm birth was present in the SGA-treated group. However, healthy females composed the control group in these studies, and the underlying disease state being treated with an SGA is an important confounder.[139] Data on pregnancy exposure with the newer SGAs (eg, asenapine, lurasidone, brexpiprazole, lumateperone, and cariprazine) are minimal or absent. While large, well-controlled studies are still needed to determine the safety of all SGAs during pregnancy, the British Association for Psychopharmacology Consensus Guidelines do not currently consider them major teratogens.[127]

The potential for antipsychotic related postnatal and gestational complications is of interest. Weight gain associated with SGAs and the potential risk of gestational diabetes should be considered in medication selection. A systematic review that included 10 studies did not find an association between SGAs collectively and gestational diabetes.[140] A retrospective cohort study reported an increased risk of gestational diabetes in individuals who continued quetiapine or olanzapine during the first 20 weeks of pregnancy versus those who discontinued those agents.[141] An increase risk was not observed with risperidone, aripiprazole, or ziprasidone which indicates that risk may differ among SGAs.[127] An increased risk of hypertension in individuals taking antipsychotics during pregnancy as well as venous thromboembolism have also been reported.[128]

Risk of neonatal EPS is increased with in utero exposure to FGAs, with effects in the infant lasting for 3 to 12 months after birth. In 2011, the FDA issued a safety announcement informing healthcare professionals that the pregnancy section of medication labels had been updated for the entire antipsychotic class, highlighting the potential risk for EPS and withdrawal symptoms in newborns exposed to antipsychotics in utero during the third trimester.[142] Symptoms of neonatal withdrawal reported to the FDA included agitation, hypertonia, hypotonia, tremor, somnolence, respiratory distress, and feeding disorder.

To date, little is known about in utero exposure to antipsychotics and neurodevelopmental teratology with most data being derived from case reports and case-series. One case-control study (*n*=76) reported a transient delay in cognitive, motor, social-emotional, and adaptive behavior in SGA-exposed infants at 2 months of age that resolved by 12 months.[143] One prospective study reported in utero exposure to antipsychotics (*n*=22) was associated with lower neuromotor screening measures at 6 months of age compared to either antidepressant exposed infants or no psychotropic exposure.[144] A population-based cohort study of 411,251 children did not find an elevated risk of autism spectrum disorder or attention deficit hyperactivity disorder with in utero exposure to SGAs.[145]

For many individuals with schizophrenia, discontinuing the antipsychotic during pregnancy may not be recommended, despite the lack of safety data. The risk of antipsychotic use must be weighed against the benefits of pharmacotherapy in pregnant individuals experiencing disorganized thoughts, delusions about change in body image or pregnancy, or who are unable to engage in prenatal care.[133] A national pregnancy exposure registry monitors pregnancy outcomes in those exposed to SGAs during pregnancy. Clinicians are encouraged to report SGA use in pregnancy through the registry to assist in gathering safety information. This registry can be accessed at: http://womensmentalhealth.org/clinical-and-research-programs/pregnancyregistry/atypicalantipsychotic.

Data regarding the antipsychotics and human milk are even more limited than their use during pregnancy. Olanzapine is the most studied antipsychotic in lactation (*n* = 170 exposures), followed by quetiapine (*n* = 14), risperidone (*n* = 8), and aripiprazole (*n* = 4). Overall, olanzapine and quetiapine have reported relative infant doses (RIDs) of less than 2%, meaning that with continued exposure to human milk, infants would only be exposed to 2% of maternal dosage overall.[146] Risperidone (+ 9-OH-risperidone) and aripiprazole have reports of slightly higher RID ranges (2.8-9.1 and 0.7-8.3, respectively).[146] Of note, treatment with aripiprazole may lead to reduced milk production as a result of reduced prolactin release.[147] Breastfeeding while on clozapine is not recommended due to the risk of severe neutropenia and seizures in the infant.[127] For all of the FGAs, the overall RID is thought to be less than 10%, which is a common threshold indicating that these medications are safe when feeding infants human milk.

Data evaluating long-term outcomes in infants exposed to antipsychotics through human milk are minimal to absent. The co-administration of chlorpromazine and haloperidol is reported to result in developmental delays at 12 to 18 months of age; however, these were not controlled studies.[127] Although most antipsychotics are not contraindicated in lactation, the lowest dosage for antipsychotics should be used, and the infant carefully monitored for antipsychotic adverse events such as EPS, sedation, seizures, and developmental delays.[127,146,147] Additional studies evaluating short- and long-term adverse effects, including developmental outcomes, of infants exposed to antipsychotics via human milk are warranted.

Medication Interactions

Most medication interactions occur because of pharmacodynamic or pharmacokinetic interactions (Tables 87-9 and 87-10). Common examples of pharmacodynamic interactions resulting in enhanced effect include the excess sedation that can occur when antipsychotics are used concomitantly with other medications that have sedative adverse effects. Additive antimuscarinic effects can also be seen when antipsychotics are used with other medications possessing antimuscarinic effects, potentially resulting in urinary retention, constipation, blurred vision, or other anticholinergic adverse effects.[148] Both combined sedative and anticholinergic effects from multiple medications can result in impaired cognition or delirium, particularly in older adults and other patients predisposed to such problems.[148] Patients are more likely to experience symptomatic orthostatic hypotension when an antipsychotic is used with other medications that cause orthostasis. Metoclopramide, a DA antagonist, is prescribed for treating esophageal reflux or gastroparesis, and patients may be more likely to experience akathisia and other EPS (including TD) if it is used concomitantly with antipsychotics.[149] Although some selective serotonin reuptake inhibitors (SSRIs) can interact with antipsychotics through enzyme inhibition, they can also interact through pharmacodynamic mechanisms. Since 5-HT$_2$ receptors are present on the presynaptic dopaminergic neuron, their activation leads to decreased DA release from the presynaptic terminal. Increased availability of 5-HT through the SSRI's effect can activate these receptors, which in turn results in decreased DA release, and adds to the dopaminolytic effects of antipsychotics.[57] In the absence of enzyme inhibition, SSRIs can still precipitate akathisia or EPS when added to a patient stabilized on an antipsychotic. Several cases of serotonin syndrome have been reported with SGAs used in combination with serotonergic agents, such as SSRIs or tramadol.[57] Another potentially dangerous interaction can occur when medications that slow myocardial conduction, and thus prolong the QTc interval, are used in combination with antipsychotics having the same effect.[57] Careful monitoring should occur with medications that prolong the QTc interval, as well as when antipsychotics with this effect are combined with diuretics.[57]

Food enhances the absorption of both ziprasidone and lurasidone, with the product labels noting a greater than twofold increase in bioavailability when the agents are given with food (Table 87-10). The exact mechanism for the impact of food on absorption is not fully understood[30,150] but simply doubling the dose in a fasted state will not necessarily double the level.[150] Therefore, ziprasidone requires administration with a 500 kcal (2,100 kJ) meal and 350 kcals (1,460 kJ) with lurasidone.[30,150] Asenapine, on the other hand, requires that food and drink be avoided for at least 10 minutes after administration to reduce the chance of the patient swallowing the medication instead of allowing for sublingual absorption, which as previously discussed, impacts bioavailability.[28,66]

TABLE 87-9

Common Potential Pharmacodynamic Interactions with Antipsychotic Medications

Mechanism of Interaction		Examples of Interacting Drugs or Other Substances		Clinical Effect
Muscarinic receptor blockade		Anticholinergics Benztropine Diphenhydramine Trihexyphenidyl		Increased risk of anticholinergic adverse reactions
Additive or synergistic sedation		*Sedatives* Benzodiazepines Concomitant AP Diphenhydramine Melatonin and melatonin agonists Mirtazapine Trazodone TCAs Hypnotics Opiates	*Anticholinergics* Benztropine Diphenhydramine Trihexyphenidyl Mirtazapine	Increased risk of sedation Lethargy Impaired cognition Impaired psychomotor activity Risk of accidents
DA antagonist use for different indication		Metoclopramide		Increased risk of EPS
Cardiovascular interactions				
	QTc prolongation	Amitriptyline Clomipramine Imipramine Citalopram Fluorquinolone antibiotics	Procainamide Quinidine	Increased risk of ECG changes and dysrhythmias
	Electrolyte changes	Diuretics		Increased risk of ECG changes and dysrhythmias
Stimulation of presynaptic 5-HT receptors on DA neuron		SSRIs		Increased EPS
Sympatholytics: α-blockade decreases NE release		Clonidine Methyldopa Prazosin Nitric oxide containing products		Increased hypotension
Increased DA receptor binding		Antipsychotics		Increased adverse medication reactions particularly EPS

DA, dopamine; ECG, electrocardiogram; EPS, extrapyramidal symptoms; 5-HT, serotonin; SSRI, serotonin selective reuptake inhibitor; TCAs, tricyclic antidepressants; NE, norepinephrine.

Data from References 27-30, 32, 37, 148, and 149.

TABLE 87-10

Common Potential Pharmacokinetic Interactions with Antipsychotic Medications

Substrate Antipsychotic and Mechanism of Interaction	Interacting Medication or Substance	Clinical Effect
Aripiprazole, *brexpiprazole*, *cariprazine*, and *iloperidone*		

Inhibition of AP metabolism (CYP2D6, CYP3A4)	*Antidepressants* Bupropion Clomipramine Doxepin Duloxetine Fluoxetine Fluvoxamine Paroxetine Sertraline *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluconazole Ketoconazole Itraconazole *Antipsychotics* Asenapine Chlorpromazine Haloperidol Perphenazine Thioridazine	*Miscellaneous* Chlorpheniramine Cimetidine Cocaine Diltiazem Diphenhydramine Cimetidine Grapefruit juice Haloperidol Hydroxyzine Methadone Quinidine Ticlopidine Verapamil	Increased AP effect and risk of adverse medication reactions
Induction of AP metabolism	*Antiseizure Medications* Carbamazepine Oxcarbazepine Phenobarbital Phenytoin	*Anti-infectives* Rifampin *Miscellaneous* Glucocorticoids Modafinil	*Herbals* St. John's wort	Decreased AP effect
Asenapine				
Inhibition of AP metabolism (CYP1A2)	*Antidepressants* Fluvoxamine	*Anti-infectives* Ciprofloxacin Fluroquinolones	*Miscellaneous* Amidarone Cimetidine	Increased AP effect and risk of adverse medication reactions
Induction of AP metabolism	*Anti-infectives* Nafcillin	*Miscellaneous* Broccoli Brussels sprouts Chargrilled meat Smoking tobacco	*Miscellaneous* Insulin Modafinil Omeprazole	Decreased AP effect
NOTE: Eating food or drinking liquids within 10 minutes of asenapine sublingual administration will decrease bioavailability				
Clozapine				
Inhibition of AP metabolism (CYP3A4, CYP1A2, CYP2D6)	*Antidepressants* Fluoxetine Fluvoxamine *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluconazole Fluroquinolones Ketoconazole Itraconazole Nafcillin	*Miscellaneous* Amidarone Cimetidine Diltiazem Grapefruit juice Haloperidol Ticlopidine Verapamil Cimetidine	Increased AP effect and risk of adverse medication reactions
Induction of AP metabolism	*Antiseizure Medications* Carbamazepine Phenobarbital Phenytoin	*Miscellaneous* Glucocorticoids Insulin Modafinil Omeprazole Smoking tobacco	*Herbals* St. John's wort *Anti-infectives* Rifampin	Decreased AP effect
Haloperidol				
Inhibition of AP metabolism (CYP2D6, CYP3A4, CYP1A2)	*Antidepressants* Bupropion Doxepin Duloxetine Fluoxetine Fluvoxamine Paroxetine Sertraline *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir Sequinavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluoconazole Fluoroquinolones Ketoconazole Itraconazole *Antipsychotics* Chlorpromazine Perphenazine	*Miscellaneous* Amiodarone Chlorpheniramine Cimetidine Diltiazem Diphenhydramine Quinidine Diphenhydramine Cimetidine Grapefruit juice Hydroxyzine Methadone Quinidine Verapamil	Increased AP effect and risk of adverse medication reactions

Induction of AP metabolism	*Antiseizure Medications* Carbamazepine Oxcarbazepine Phenobarbital Phenytoin	*Anti-infectives* Nafcillin Rifampin *Miscellaneous* Broccoli Brussels sprouts Chargrilled meat Glucocorticoids Insulin Modafinil Omeprazole	*Herbals* St. John's wort Tobacco smoking	Decreased AP effect
Olanzapine				
Inhibition of AP metabolism (CYP3A4 and CYP1A2)	*Antidepressants* Fluoxetine (norfluoxetine) Fluvoxamine *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluoconazole Fluoroquinolones Ketoconazole Itraconazole	*Miscellaneous* Amiodarone Cimetidine Diltiazem Cimetidine Grapefruit juice Verapamil	Increased AP effect and risk of adverse medication reactions
Induction of AP metabolism	*Antiseizure Medications* Carbamazepine Oxcarbazepine Phenobarbital Phenytoin *Anti-infectives* Nafcillin Rifampin	*Miscellaneous* Broccoli Brussels sprouts Chargrilled meat Glucocorticoids Insulin Modafinil Omeprazole	*Herbals* St. John's wort Smoking tobacco *HIV protease inhibitors* Efavirenz Nevirapine	Decreased AP effect
Paliperidone				
The bioavailability of paliperidone is significantly increased when it is taken with food. Although this could increase paliperidone effect, including adverse effects, the clinical significance is undetermined. Only potent CYP3A4 (eg, carbamazepine, rifampin, St. John's wort) inducers appear to increase paliperidone metabolism and affect dose requirements.				
Lurasidone, *lumateperone*, and *quetiapine*				
Inhibition of AP metabolism (CYP3A4)	*Antidepressants* Fluoxetine (norfluoxetine) Fluvoxamine Nefazodone *HIV protease inhibitors* Indinavir Nelfinavir Ritonavir Sequinavir	*Anti-infectives* Ciprofloxacin Clarithromycin Erythromycin Fluoconazole Ketoconazole Itraconazole	*Miscellaneous* Amiodarone Cimetidine Diltiazem Grapefruit juice Verapamil	Increased AP effect and risk of adverse medication reactions
Induction of AP metabolism	*Antiseizure Medications* Carbamazepine Oxcarbazepine Phenobarbital Phenytoin	*Anti-infectives* Rifampin *Miscellaneous* Glucocorticoids Modafinil	*Herbals* St. John's wort *HIV protease inhibitors* Efavirenz Nevirapine	Decreased AP effect
NOTE: Lurasidone AUC and Cmax increase by two- and threefold when given with at least 350 calories (1,460 J) of food regardless of fat content. NOTE: Lumateperone is metabolized through multiple different pathways, but interactions have been found with moderate to potent CYP3A4 inhibitors and a CYP3A4 inducer.				
Perphenazine and *risperidone*				
Inhibition of AP metabolism (CYP2D6)	*Antidepressants* Bupropion Clomipramine Doxepin Duloxetine Fluoxetine Paroxetine Sertraline *Antipsychotics* Chlorpromazine Haloperidol (reduced haloperidol)	*Miscellaneous* Amiodarone Cimetidine Chlorpheniramine Cocaine Diphenhydramine Cimetidine Haloperidol Hydroxyzine Methadone Quinidine		Increased AP effect and risk of adverse medication reactions

	Perphenazine			
Induction of AP metabolism (via CYP3A34, a minor pathway for risperidone)	*Miscellaneous* Dexamethasone	*Anti-infectives* Rifampin		Decreased AP effect
NOTE: Because risperidone's metabolite formed through CYP2D6 metabolism is active (paliperidone), the clinical significance of pharmacokinetic interactions with risperidone is unclear.				
Ziprasidone				
The bioavailability of ziprasidone is increased twofold when it is taken with food. Consistent administration with food is recommended.				

AP, antipsychotic; AUC, Area Under the Curve; Cmax, maximum plasma concentration.

Data from References 27-33, 57, and 148-150.

Asenapine inhibits CYP2D6, and is the only SGA that has been shown to significantly affect the pharmacokinetics of other medications.[28] Table 87-6 lists the known major pathways involved in the metabolism of SGAs. Risperidone is largely metabolized by CYP2D6 to its active metabolite, 9-OH-risperidone (paliperidone), which is thought to have a similar pharmacodynamic profile.[57] Although paliperidone is primarily eliminated renally unchanged, potent inducers of CYP3A4 can cause a potential need for dosage adjustment.[57,66] For asenapine, CYP1A2 is the primary isoenzyme responsible for metabolism with CYP3A4 also being a significant pathway.[57,66]

Based on current information, inhibitors of CYP1A2 have the greatest potential for causing interactions with clozapine and olanzapine, and some concern with asenapine.[57] Examples include cimetidine, fluvoxamine, and fluoroquinolone antibiotics (ie, ciprofloxacin) to varying degrees. To date, however, no serious inhibition interactions have been reported with olanzapine, which may be a result of olanzapine's wide therapeutic index; however, carbamazepine has been reported to increase olanzapine elimination by as much as 50%.[57] Cigarette smoking is a potent inducer of CYP1A2, and one would expect lower mean olanzapine serum concentrations in smokers compared with those in nonsmokers.

Because of the risk of seizures with higher clozapine tissue concentrations, interactions that inhibit clozapine's metabolism are potentially significant. In particular, fluvoxamine increases clozapine serum concentrations by an average of two- to threefold and up to fivefold.[57] Ciprofloxacin, other fluroquinolones, fluoxetine, and erythromycin can also increase clozapine serum concentrations.[57] As smoking has been associated with a 33% to 55% increase in clozapine clearance,[57] smoking cessation can result in increased clozapine serum concentration that may increase the risk of seizures.[66] Carbamazepine can also induce clozapine metabolism and lead to lower serum concentrations.[57]

A study with the potent CYP3A4 inhibitor ketoconazole showed minimal effects on ziprasidone single-dose pharmacokinetics, with only a 33% mean increase in the ziprasidone area under the time-versus-concentration curve.[57] These results are consistent with data suggesting that aldehyde oxidase is the major metabolic pathway for ziprasidone, with only 30% to 35% being metabolized by CYP3A4.[57]

Modest elevations of aripiprazole serum concentrations occur in the presence of ketoconazole or quinidine, which inhibit CYP3A4 and 2D6, respectively. Ketoconazole has a profound effect on decreasing lurasidone metabolism, and it is recommended that they not be used concomitantly.[30,57] Carbamazepine has been reported to decrease aripiprazole serum concentrations.[57]

Since iloperidone is metabolized through CYP2D6 and 3A4, its clearance can be impaired by inhibitors of these pathways. These types of interactions have the potential to be clinically significant. For example, it is recommended that the iloperidone dose be decreased by 50% when used with CYP2D6 inhibitors such as fluoxetine or paroxetine.[27,57]

Multiple enzymes are responsible for the metabolism of lumateperone. AKR1C1 is the predominant enzyme metabolizing lumateperone to the alcohol metabolite IC200131.[151] Multiple other enzymes are involved in its metabolism including CYP3A4. Dosage adjustments should occur in patients taking moderate to strong CYP3A4 inhibitors or inducers.[33]

Personalized Pharmacotherapy

Pharmacotherapy must be individualized for each person with schizophrenia. Apart from iloperidone, no laboratory tests are generally available that will predict a patient's response to treatment. Past response to treatment, potential adverse effects, patient personal preference, and medication price are the primary variables that should be used in selecting an antipsychotic that is included in stages 1A, 1B, or 2 of the treatment algorithm. In the CATIE study, the number one reason for medication discontinuation was the patient not wanting to take that medication any more, and the second most common reason was adverse effects.[17] These two factors should be carefully considered in antipsychotic selection and medication dosage must be individualized within the usual dose ranges. Careful consideration must also be given to concomitant medications that may interact with the antipsychotic and necessitate a change in dosage.

Preliminary data suggest a relationship between different genetic markers and clinical improvement as well as QTc prolongation in patients treated with iloperidone.[27,64] Substantial interest exists regarding the potential utility of pharmacogenetic monitoring in the pharmacotherapy of schizophrenia. Increasing relationships are being identified between specific genetic variation in relation to both the pharmacodynamics and pharmacokinetics of different antipsychotics. However, no convincing data have demonstrated that clinical outcomes are superior when using routine pharmacogenetic monitoring in the pharmacotherapy of schizophrenia, nor have cost-effectiveness studies of its use been performed.[64,65] Although promising for the future, routine pharmacogenetic monitoring in all patients with schizophrenia is not currently recommended. However, it may be useful in select patients. For example, if a patient appears particularly sensitive to developing EPS when treated with antipsychotics metabolized through CYP2D6, it might be useful to perform pharmacogenetic testing to determine whether the patient is a poor CYP2D6 metabolizer. If so, antipsychotics metabolized through CYP2D6 should be used at lower doses, or the patient switched to an antipsychotic not metabolized by CYP2D6.[64] Clinicians should consult accepted guidelines, such as those by the Clinical Pharmacogenetics Implementation Consortium (https://cpicpgx.org/), before utilizing pharmacogenetic data.[67]

Given that no antipsychotic has proven superiority regarding efficacy in the treatment of schizophrenia (with the exception of clozapine in treatment resistance), cost should be a factor in antipsychotic selection. Many antipsychotics have generic equivalents available, and this should be a factor in selecting an antipsychotic (Table 87-9).

Evaluation of Therapeutic Outcomes

⑩ Assessment of response has traditionally been done subjectively or empirically (a relative sense of how the clinician feels the patient is doing). A formal mental status exam (MSE) is used to structure the patient interview and focus on items related to appearance, mood, sensorium, intellectual functioning, and thought processes. However, the MSE is neither specific nor quantitative for the measurement of medication response. Clinicians should be trained to use simple, standardized psychiatric rating scales to assist in objectively rating patient medication responses.[152] The Brief Psychiatric Rating Scale (BPRS) and the Positive and Negative Syndrome Scale (PANSS) were developed for use in clinical trials as research tools to quantify symptom improvement seen with antipsychotic treatment (see Chapter e81). Objectively, a numeric indicator (eg, 20%, 30%, or 40% reduction in BPRS score) has been used to quantify overall symptom reduction and classify patients according to different degrees of response. However, these types of rating scales are too long and unwieldy to be routinely used within the time constraints of most clinical practices. Symptom scales used in clinical practice must be sufficiently brief to be used during an ordinary clinic visit (eg, 15-30 minutes) while measuring both positive and negative symptoms, and being sufficiently representative of overall symptomatology. The four-item Positive Symptom Rating Scale (PSRS) and the four-item Brief Negative Symptom Assessment (BNSA) are brief scales that meet such criteria (Table 87-11).[152] A brief rating scale of positive symptoms, such as the PSRS, should be used at baseline before starting pharmacotherapy, and at each time response to pharmacotherapy is assessed.

TABLE 87-11

Brief Clinical Assessments for Monitoring Antipsychotic Response in Schizophrenia

Four-Item Positive Symptom Rating Scale (PSRS)								
Use each item's anchor points to rate the patient								
1. Suspiciousness	NA	1	2	3	4	5	6	7
2. Unusual thought content	NA	1	2	3	4	5	6	7
3. Hallucinations	NA	1	2	3	4	5	6	7
4. Conceptual disorganization	NA	1	2	3	4	5	6	7
Each item is scored from 1 (not present) to 7 (extremely severe)	SCORE:							
Brief Negative Symptom Assessment (BNSA)								
Use each item's anchor points to rate the patient								
1. Prolonged time to respond	1	2	3	4	5	6		
2. Emotion: Unchanging facial expression, blank, expressionless face	1	2	3	4	5	6		
3. Reduced social drive	1	2	3	4	5	6		
4. Poor grooming and hygiene	1	2	3	4	5	6		
Each item is scored from 1 (normal) to 6 (severe)	SCORE:							

[a] NA, not able to be assessed.

Data from Reference 152.

Similarly, the pharmacotherapeutic plan should include specific monitoring parameters for adverse medication reactions (Table 87-12). The plan should include how the potential reactions will be evaluated, and the frequency of assessment. Given the risk of weight gain, diabetes, and lipid abnormalities associated with many of the SGAs, a consensus task force led by the American Diabetes Association recommends the following baseline parameters before beginning antipsychotics: family history, weight, height, BMI, waist circumference, blood pressure, fasting plasma glucose, and fasting lipid profile.[83] They also recommend follow-up monitoring of these parameters after beginning or changing SGAs. Weight should be monitored monthly for the first 3 months and quarterly thereafter. The other parameters should be assessed at the end of 3 months, and if normal, then at least annually. Self-assessments can be a useful adjunct in treating the patient. Although the patient with schizophrenia may not always be accurate in evaluating symptom severity, the use of patient self-assessments increases patient engagement in care, enhances therapeutic alliance, and gives the clinician an opportunity to identify misconceptions the patient may have regarding symptoms associated with the illness, adverse medication reactions, and the like.[55] Traditionally, clinicians have often accepted partial symptom response in schizophrenia as success, and have not been aggressive in attempting to achieve greater symptomatic remission. The advent of multiple different SGAs with varying tolerability profiles should encourage clinicians to be more assertive in attempting to achieve symptom remission. This is consistent with an increasing focus on remission as a goal of treatment and the evolving emphasis on consumerism in the care of patients with severe mental illness.[54]

TABLE 87-12

Antipsychotic Adverse Reactions and Monitoring Parameters

Adverse Reaction	Monitoring Parameter	Frequency	Comments
Adverse Reaction Monitoring Parameters for All Antipsychotic Medications			
Akathisia	Ask about restlessness or anxiety. Observe patient for restlessness. Barnes Akathisia Scale can also be used	Every visit	
Anticholinergic adverse effects	Ask patient about constipation, blurry vision, urinary retention, or unusual dry mouth	Every visit	
Glucose intolerance	FBS or HbA1c	At baseline, after 3 months, and if normal, then annually	
Hyperlipidemia	Lipid profile	At baseline, after 3 months, and if normal, then annually	
Orthostatic hypotension	Ask patient about dizziness on standing. If present, check BP and HR in sitting and standing positions	Every visit	The degree of orthostatic change in BP to produce symptoms varies. In general, a BP change of 20 mm Hg or more is significant
Hyperprolactinemia	In females, ask about expression of milk from the breast and menstrual irregularities. In males, ask about breast enlargement or expression of milk from nipples. If symptoms present, check serum prolactin level	Every visit	In the absence of symptoms, there is no need to monitor serum prolactin
Sedation	Ask patient about unusual sedation or sleepiness	Every visit	
Sexual dysfunction	Ask patient about decreased sexual desire, difficulty being aroused, or problems with orgasm	Every visit	Patients with schizophrenia have more sexual dysfunction than the normal population. Compare symptoms with medication-free state
Tardive dyskinesia	Standardized rating scale such as the AIMS or the DISCUS	At baseline, and then every 6 months for FGAs and every 12 months for SGAs	
Weight gain	Measure body weight, BMI, and waist circumference	BMI every visit for 6 months and at least quarterly thereafter	Waist circumference is the single best predictor of cardiac morbidity
Adverse Reaction Monitoring Parameters for Specific Antipsychotics			
Agranulocytosis	Absolute neutrophil counts (ANC)	At baseline, weekly for 6 months, then every 2 weeks for 6 months, and then monthly	Clozapine only
Sialorrhea or excess drooling	Ask patient about problems with excess drooling, waking in the morning with a wet ring on his or her pillow. Visual observation of the patient for drooling	Every visit	Clozapine only
Bronchospasm, respiratory distress, respiratory depression, respiratory arrest	Before administration, patients must be screened for a history of asthma, chronic obstructive pulmonary disease, or other lung disease associated with bronchospasm. Monitor patient every 15 minutes for a minimum of 1 hour after medication administration for signs and symptoms of bronchospasm (ie, vital signs and chest auscultation). Only one 10-mg dose can be given every 24 hours	Every dose administration	Inhaled loxapine only. Can only be administered in approved healthcare facilities registered in REMS program
Post injection sedation/delirium syndrome	Observation of the patient for at least 3 hours after medication administration. Monitor for possible sedation, altered level of consciousness, coma, delirium, confusion, disorientation, agitation, anxiety, or other cognitive impairment	Every dose administration	Long-acting olanzapine pamoate monohydrate only. Can only be administered in approved healthcare facilities registered in REMS program

FBS, fasting blood sugar; AIMS, abnormal involuntary movement scale; DISCUS, dyskinesia identification system condensed user scale; FGA, first-generation antipsychotic; SGA, second-generation antipsychotic.

CONCLUSION

Schizophrenia is a neurodevelopmental disorder whose etiology is currently unknown. A multitude of medications, primarily working through dopamine, serotonin, and glutamatergic antagonism, have been developed to treat symptoms associated with this syndrome. Although there is no cure for schizophrenia, lifelong antipsychotic use combined with comprehensive psychosocial services can allow many of these individuals to function. However, medication adherence can be challenging, and the use of long-acting injectable antipsychotics combined with psychosocial services designed to address engagement with treatment can promote adherence. Antipsychotic medications have a multitude of potential adverse reactions, and prudent monitoring is necessary. As the common core symptoms associated with schizophrenia (positive, negative, and cognitive) vary among person to person, continual evaluation of therapeutic outcomes focusing on overall functioning and quality of life is necessary.

NRG1	neuregulin 1
NRXN1	synaptic protein neurexin 1
PANSS	Positive and Negative Symptom Scale
PDSS	post injection delirium/sedation syndrome
PET	positron emission tomography
PORT	Patient Outcomes Research Team
PSRS	Positive Symptom Rating Scale
RAISE	Recovery After Initial Schizophrenia Episode
REMS	Risk Evaluation and Mitigation Strategy
RID	relative infant dose
RNA	ribonucleic acid
SCD	sudden cardiac death
SEs	side effects
SGA	second-generation antipsychotic
SNP	single nucleotide polymorphism
SSRI	selective serotonin reuptake inhibitor
STRIDE	Reducing Weight and Diabetes Risk in an Underserved Population
T2DM	type 2 diabetes mellitus
TCA	tricyclic antidepressant
TD	tardive dyskinesia
UK	United Kingdom
VMAT2	vesicular monoamine transporter-2
VTE	venous thromboembolism
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. Which of the following is the *most accurate* statement regarding the potential etiology of schizophrenia?
   A. Schizophrenia is likely caused by the affected individual having an oppressive mother during early childhood development.
   B. Genetics studies suggest a Mendelian genetic relationship for developing schizophrenia.
   C. PET studies indicate that schizophrenia is a degenerative brain disorder.
   D. Schizophrenia may be caused by variety of genetic polymorphisms in combination with an environmental assault in utero.
2. A theory regarding the pathophysiology of schizophrenia suggests that the predrome phase of the illness is associated with
   A. Excessive synthesis and release of serotonin from presynaptic receptors
   B. Decreased density of D_2 receptors in the mesocaudate
   C. Glutamatergic synaptic dysfunction resulting in a glutamatergic signaling defect
   D. Hyperactivity of gamma-amino-butyric acid (GABA) pathways
3. Symptom domains that are characteristic of a diagnosis of schizophrenia include all of the following *except*:
   A. Cognitive impairment
   B. Depression
   C. Negative symptoms
   D. Positive symptoms
4. The four core interventions that have been shown to improve the quality of life in individuals with early schizophrenia include all of the following *except*:
   A. Family psychoeducation
   B. Psychoanalysis
   C. Resilience-focused individual therapy
   D. Supported employment and education
5. Which of the following *most accurately* reflects the initial workup (ie, evaluation) of a patient suspected of having schizophrenia?
   A. Mental status exam, physical exam, neurological exam, social history, laboratory workup, and PET scan
   B. Mental status exam, physical exam, neurological exam, social history, laboratory workup, and MRI scan
   C. Mental status exam, physical exam, neurological exam, social history, family history, and a CSF homovanillic acid (HVA) level
   D. Mental status exam, physical exam, neurological exam, family history, social history, and laboratory workup
6. Based upon both efficacy and safety, which of the following are evidence-based first-line pharmacotherapy options in a patient experiencing the first psychotic episode associated with schizophrenia?
   A. Aripiprazole, risperidone, and ziprasidone
   B. Perphenazine, quetiapine, and risperidone

C. Haloperidol, olanzapine, and quetiapine

D. Aripiprazole, lurasidone, and ziprasidone

7. O.Y. is a 27-year-old with schizophrenia admitted for their second psychiatric hospitalization. Treated with risperidone, the patient presents in an acute psychotic episode with fulminate suicidal ideation and a serious suicide attempt prior to hospitalization. Based on this information, which of the following antipsychotics would be the *best choice* for this patient at the present time?

A. Clozapine

B. Haloperidol

C. Lurasidone

D. Risperidone

8. Which of the following are interventions that may increase the treatment adherence of individuals with schizophrenia?

A. Cognitive behavioral therapy

B. Involvement of families

C. Patient information about the disorder and treatment

D. All of the above may be helpful

9. B.W. is a 33-year-old with schizophrenia in an acute exacerbation who has had previous unsuccessful medication courses with risperidone and olanzapine. The risperidone was at a maximum dose of 6 mg/day for 6 months, and olanzapine was for a maximum dose of 20 mg daily for 9 months. Patient adherence with treatment was deemed to be adequate during the previous medication trials. Based on the available information, which of the following is the *most appropriate* medication intervention at the present time?

A. Asenapine

B. Cariprazine

C. Clozapine

D. Lumateperone

10. The rapid on, rapid off theory of atypicality is *best associated* with which of the following antipsychotics?

A. Aripiprazole

B. Olanzapine

C. Quetiapine

D. Risperidone

11. C.H. is a 25-year-old with a diagnosis of schizophrenia previously treated with haloperidol and risperidone. Since starting risperidone, the patient has gained about 8 pounds and inquires about a change in medication to an antipsychotic that is less likely to cause weight gain. Based on this request, which of the following would be the *best* choice?

A. Ziprasidone

B. Chlorpromazine

C. Clozapine

D. Olanzapine

12. J.B. is a 34-year-old with a diagnosis of schizophrenia previously treated with monotherapy trials of haloperidol, perphenazine, and fluphenazine decanoate. J.B. has had persistent difficulty with extrapyramidal side effects, including parkinsonian symptoms and dystonic reactions. These symptoms have been treated with benztropine and diphenhydramine, but breakthrough EPS symptoms still occur. Which of the following would be the *poorest* antipsychotic treatment option for this patient?

A. Risperidone

B. Olanzapine

C. Quetiapine

D. Brexpiprazole

13. B.C. is a 35-year-old with a diagnosis of schizophrenia. In the past, B.C. has taken haloperidol and risperidone and experienced parkinsonian symptoms on both of these medications. After taking olanzapine 15 mg daily for the past 6 months, B.C. presented to primary care for complaints of fatigue, excessive thirst, and frequent urination. Fasting blood glucose is 180 mg/dL (10.0 mmol/L). Although psychotic symptoms are reasonably well controlled, the clinician deems that it is best to change antipsychotic medication. Based on the information above, which of the following would be the *best* choice?

A. Aripiprazole

B. Clozapine

C. Haloperidol

D. Quetiapine

14. D.D. is a 66-year-old with a diagnosis of schizophrenia, hypertension, and gastroesophageal reflux disorder (GERD) and medication regimen includes quetiapine, hydrochlorothiazide, metoclopramide, and ranitidine. Over the past 3 months, D.D. has developed a shuffling gait, drooling, and a resting tremor. In screening the patient's profile, which of the following might represent a drug interaction?

    A. Ranitidine is inhibiting the metabolism of quetiapine, causing the patient to develop Parkinson's symptoms.

    B. Hydrochlorothiazide alteration of quetiapine elimination in the kidneys is resulting in Parkinson's symptoms.

    C. Metoclopramide's dopaminergic blockade in combination with quetiapine is producing Parkinson's symptoms.

    D. Metoclopramide alteration of quetiapine metabolism is causing Parkinson's symptoms.

15. After initiating a new antipsychotic in a patient with schizophrenia, appropriate routine monitoring parameters are *best* reflected by:

    A. Brief standardized clinical rating scales, weight, blood pressure, waist circumference, blood glucose, serum lipids

    B. Positive and Negative Symptom Rating Scale, weight, antipsychotic serum concentration, waist circumference, blood glucose, serum lipids

    C. Brief standardized clinical rating scales, weight, blood pressure, blood glucose, serum lipids, electrocardiogram

    D. Positive and Negative Symptom Rating Scale, weight, blood pressure, blood glucose, serum lipids, white blood cell count, electrocardiogram

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Schizophrenia is a neurodevelopmental disorder that is associated with genetic polymorphism of multiple different genes combined with an unknown environmental risk factor. The environmental risk likely occurs in utero or in the perinatal period (see "Etiology" section).

2. **C.** The predrome phase is a high-risk period for the development of schizophrenia. Glutamatergic dysfunction may precede abnormalities in dopaminergic dysfunction. Glutamatergic dysfunction results in decreased GABA activity (prodrome phase), and this results in decreased inhibition of dopaminergic transmission. The actual increase in dopaminergic transmission may be associated with onset of the first psychotic episode (see "Pathophysiology" section).

3. **B.** Although depression is commonly seen in individuals with schizophrenia, it is not one of the core symptoms required for the diagnosis of the syndrome (see "Clinical Presentation" section).

4. **B.** Effective psychosocial interventions focus on improving the individuals' ability to function on a daily basis, including methods to promote adherence with medication and other treatment regimens. Therapy is typically focused on improving the person's resilience, daily psychosocial functioning, and treatment adherence. However, cognitive therapy that focuses on the needs of a person with schizophrenia may be of benefit. Classic psychoanalysis has no evidence to support its use in individuals with schizophrenia (see Table 87-4).

5. **D.** The initial workup for an individual suspected of having schizophrenia is focused on eliminating other potential causes of psychosis (eg, medical disorder, substance use), and establishing a baseline for medical monitoring of the patient. The mental status and history focus on making sure that the clinical features are consistent with the *DSM-5* criteria for schizophrenia. There are no laboratory tests or imagining studies that are diagnostic for schizophrenia.

6. **A.** Aripiprazole, risperidone, and ziprasidone have all been studied during the initial or first episode of schizophrenia, and all have similar efficacy. The one study with quetiapine during the first episode showed a higher relapse rate than in the studies with the other three medications. While olanzapine has good efficacy during the first episode, it has the highest incidence of weight gain and other metabolic side effects and is not recommended for first episode. The other medications listed have not been studied during first episode (see Fig. 87-1).

7. **A.** The general recommendation is to use clozapine in a patient who has failed to have adequate improvement in symptoms after two adequate monotherapy trials (dose and duration) with other antipsychotics. However, clozapine is the only antipsychotic that has evidence of decreasing suicide in highly suicidal patients, and its use is indicated earlier in treatment for treating suicidality associated with schizophrenia. Clozapine would be the best choice for this particular patient (see Fig. 87-1).

8. **D.** All of the listed psychosocial interventions have evidence for improving treatment adherence in individuals with schizophrenia, and outcomes are thought to be better when they are used in combination. Comprehensive psychosocial services in combination with appropriate medication are necessary to achieve the best clinical outcomes in persons with schizophrenia (see Table 87-4).

9. **C.** Clozapine is the only antipsychotic that has evidence for efficacy in individuals with "treatment-resistant schizophrenia." Treatment resistance is most commonly defined as inadequate improvement in clinical symptoms with adequate monotherapy trials (dose and duration) with two different antipsychotics.

10. **C.** All available antipsychotics bind to D_2 receptors rapidly (rapid on). However, of available antipsychotics only clozapine and quetiapine have evidence for rapid disassociation from the D_2 receptor (rapid off). Based on this theory, only relatively brief binding to dopaminergic D_2 receptors is necessary for antipsychotic effect while longer binding (slow off) is thought to be associated with greater risk of extrapyramidal side effects. While there is some evidence in humans, utilizing PET scan technology, to support this theory, it is important to emphasize that it is still largely theoretical (see Table 87-5).

11. **A.** Of the listed antipsychotics, ziprasidone is associated with the least weight gain. Olanzapine causes the most weight gain, and both chlorpromazine and quetiapine are associated with more weight gain than ziprasidone (see Table 87-7).

12. **A.** Of the second-generation antipsychotics listed, risperidone has the greatest risk of extrapyramidal side effects. The risk of EPS with risperidone is dose related, and at doses greater than 6 mg daily, risperidone loses most of its atypical antipsychotic profile (see Table 87-7).

13. **A.** Patient B.C. is experiencing glucose intolerance, possibly associated with olanzapine. With a history of EPS with the use of haloperidol and risperidone, both of those medications would be a poor choice of antipsychotics. B.C. does not appear to have treatment-resistant symptoms, and clozapine is also associated with significant weight gain and metabolic disturbances. Of the antipsychotics listed, aripiprazole has the least risk of both causing EPS and producing metabolic disturbances.

14. **E.** Metoclopramide is a D_2 receptor antagonist and can cause EPS, including pseudoparkinsonism. The risk of this is higher in older individuals. Since both metoclopramide and quetiapine have D_2 receptor antagonist properties, the two medications could have a pharmacodynamic additive effect increasing the risk for Parkinson's symptoms. Given that there are a number of therapeutic alternatives available for treating GERD, the use of metoclopramide should be avoided in older individuals and in combination with antipsychotics

15. **A.** The use of brief objective rating scales helps in evaluating clinical response to antipsychotics. In particular, brief rating scales can be useful in monitoring partial response and changes in symptoms with changes in the pharmacological regimen. The other rating scales listed are longer rating scales primarily used in clinical research. Because of the effects of antipsychotics on weight and other metabolic parameters, it is important to monitor weight, blood pressure, waist circumference, blood glucose, serum lipids. These parameters need to be monitored at baseline before starting medications, as well as periodically after medications are started. If base line monitoring parameters are not obtained, it is challenging to determine whether changes are drug related (see Table 87-11).

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 88: Depressive Disorders

Amy M. VandenBerg

KEY CONCEPTS

KEY CONCEPTS

1. Multiple guidelines are available to guide the treatment of major depressive disorder (MDD), including medication management. Clinicians treating individuals with MDD should be familiar with key tenets of these guidelines.

2. Other potential causes of symptoms such as medical conditions, medications, and other substances must first be ruled out when evaluating a patient for a diagnosis of MDD.

3. The goals of treatment for MDD are the resolution of current symptoms (ie, remission) and the prevention of further episodes of depression (ie, relapse or recurrence).

4. When counseling patients with MDD who are receiving traditional antidepressant medications, the patient should be informed that transient adverse medication reactions might occur initially, while the symptoms of depression may take 2 to 4 weeks to improve and up to 3 months for full resolution. Adherence to the treatment plan is essential for a successful outcome, and tools to help increase medication adherence should be discussed with each patient.

5. Since available antidepressants are considered equally efficacious for MDD, factors such as comorbid medical conditions, age, adverse effect profile, and past history of response are used to guide medication selection.

6. When determining if a particular medication is ineffective for a patient, it is essential to evaluate the dose and duration of treatment as well as patient adherence to the medication.

7. Novel antidepressants that target GABA and glutamate systems may have a more rapid and transient effect on symptoms. They are typically used in conjunction with traditional antidepressants for refractory symptoms.

8. Pharmacogenetic tests are now commercially available. Resources are available toguide their use when clinicians are presented with testing results as it relates to antidepressant treatment of MDD.

9. When evaluating antidepressant response, the clinician must consider quality-of-life issues, such as social, and occupational functioning in addition to target signs and symptoms. The tolerability of the agent should also be assessed due to the occurrence of adverse medication reactions that may lead to medication nonadherence. This is especially important in cases of recurrent episodes and long-term medication management.

- Patient characteristics (eg, age, sex, gender identity, race, pregnancy status)
- Current and past medical/psychiatric history (including information on first-degree family members)
- Past medication history, including medications not tolerated and any medication allergies (also collect on first-degree family members)
- Social history (eg, tobacco, ethanol, and other substance use as well as social supports and/or stressors)
- Current medications including over-the-counter (OTC), herbal products, dietary supplements, and medical or recreational cannabis use
- Objective data
  - Blood pressure, heart rate, weight
  - Labs including thyroid function tests, serum creatinine, complete blood count (CBC), liver function tests, urine toxicology screen, blood alcohol level, medication serum concentrations, and pharmacogenomics testing if available
  - Reported symptoms of depression or other rating scale assessment (eg, Patient Health Questionnaire 9 [PHQ-9], Beck Depression inventory [BDI]) (Tables 88-1 and 88-2 and Chapter e81, “Evaluation of Psychiatric Illness”)

Assess

- Suicidality (eg, Columbia-Suicide Severity Scale)
- Severity of illness/need for hospitalization
- Impact of substance use on symptoms and whether a substance use disorder is contributing to symptoms
- Presence of physical conditions that may overlap with depression symptoms (eg, pain resulting in insomnia or limited activity, gastrointestinal symptoms resulting in weight loss) or medications that may be contributing to depressive symptoms (Table 88-1)
- Past response and adherence (personal or family) to antidepressant medications

- Ability/willingness to follow up with psychiatry services including antidepressant medication management, cognitive behavioral therapy (CBT), outpatient groups
- Barriers to participation in medication management or CBT
- Barriers to adjunctive treatments (eg, exercise, stretching, yoga)
- Pharmacogenomics testing results

Plan*

- Medication therapy regimen including specific agent(s), dose, frequency, and titration plan if applicable (Table 88-3)
- Monitoring parameters including efficacy (looking for some improvement in 2-4 weeks), safety (change in suicidality), and adverse medication reactions (may be seen in first 1-2 weeks of treatment) (Table 88-11)
- Patient education (eg, purpose of treatment, medication-specific information, medication adherence, and review of laboratory/pharmacogenomics results)
- Patient education regarding self-monitoring, when to call the clinic with questions or concerns, and when to seek emergency medical attention (eg, suicidality)
- Obtain release of information to gather collateral information (eg, family members, therapists, medical providers)
- Nonpharmacological interventions (eg, diet, exercise, mindfulness)
- Make referrals to other providers when appropriate (eg, neurologist, pain specialist, substance use disorder treatment)
- Potential for medication interactions (Tables 88-5, 88-9 and 88-10)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching to maximize adherence
- Schedule follow-up to monitor an assess medication effectiveness (eg, PHQ-9, BDI) and adherence to treatment plan, including therapeutic medication monitoring when appropriate.

Follow-Up: Monitor and Evaluate

- Resolution of depressive symptoms using standardized rating scales
- Presence of adverse medication reactions (Table 88-11)
- Laboratory follow-up when indicated (eg, sodium, liver function tests)
- Patient adherence to treatment plan based in multiple sources of information (eg, medication refill records, patient/caregiver report)
- Consider scheduling early or more frequent (every 1-2 weeks) follow-up visits after initiating therapy to monitor response and behavioral risks such as suicidality. Reevaluate initial response at 2 to 4 weeks and again at 8 to 12 weeks. Reevaluate treatment plan quarterly and reevaluate duration of therapy after patient achieves remission

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the TED talk entitled Depression the Secret We Share by Andrew Solomon. This talk provides an engaging patient perspective on the experience of depression including Solomon's own experiences and that of others he interviewed.

Alternatively, watch "Pharmacology – Antidepressants – SSRIs, SNRIs, TCAs, MAOIs, lithium (Made Easy)" at https://www.youtube.com/watch?v=T25jvLC6X0w. This 19-minute video provides a brief visual narrated overview of the monoamine theory of depression and mechanisms of commonly used antidepressant medications.

INTRODUCTION

Major depressive disorder (MDD) is diagnosed when an individual experiences one or more major depressive episodes without a history of mania or hypomania. A major depressive episode and MDD are defined by the criteria listed in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*).[1] Depression is associated with significant functional disability, morbidity, and mortality. Antidepressants, such as the selective serotonin reuptake inhibitors (SSRIs), are equally effective and better tolerated than older agents, such as the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs). While depressive episodes also occur in bipolar disorder, this chapter focuses exclusively on the diagnosis and treatment of MDD.

① Three key evidence-based guidelines on the assessment and management of MDD are available to assist the clinician. The American Psychiatric Association *Practice Guideline for the Treatment of Patients with Major Depressive Disorder*, Third Edition (2010) (available at www.psych.org) is a practical guide to the management of MDD based on both available data and clinical consensus.[2] The updated British Association of Psychopharmacology (BAP) *evidence-based guidelines for treating depressive disorders with antidepressants* (2015) provide recommendations for antidepressant treatment of MDD.[3] Finally, the Canadian Network for Mood and Anxiety Treatments (CANMAT) 2016 *Clinical Guidelines for the management of adults with major depressive disorder* outlines evidence-based pharmacological treatments for MDD.[4] These three guidelines have many similarities in recommendations.

EPIDEMIOLOGY

While the actual prevalence of depressive disorders, including undiagnosed cases, is unknown, the estimated rate has increased over the past 25 years, with additional increases since 2020.[5–8] Overall, the lifetime prevalence of depression is estimated at 7% to 15% with rate in females 1.5- to 2.5-fold higher than males.[2,3] In looking at non-sex factors, the prevalence of depression is highest in those less than 60 years of age, within non-White populations, and in individuals at high poverty levels compared to White populations over the age of 60 without poverty.[9] Intersectionality, or the study of how different social classes intersect, and its relationship to depression epidemiology is becoming a high priority field of study. Adolescent depression is increasingly common with an annual prevalence (2015) of 19.4% in females and 6.4% in males between 12 and 17 years of age (up from 13.1% and 4.5%, respectively, in 2004).[2,10] In addition, transgender and non-gender conforming individuals are also at risk for increased mental health issues. In particular adolescents in these groups with poor social support report a higher degree of suicidal ideation and attempts.[11]

Depressive disorders and suicide tend to occur within families. Approximately 8% to 18% of patients with MDD have at least one first-degree relative (father, mother, brother, or sister) with a history of depression, compared with 5.6% of those without depression.[12] First-degree relatives of patients with depression are 1.5 to 3 times more likely to develop depression than those without the family history.[4,12] The heritability of liability for MDD has been estimated at 37%, with the remaining 63% of the variance in liability was due to individual-specific environment (eg, high stress, trauma).[12] Therefore, MDD is relatively common, and occurs more frequently in females than in males, and prevalence is influenced by both genetic and environmental factors.

ETIOLOGY

The etiology of depressive disorders is too complex to be explained by a single social, developmental, or biologic theory. Several factors appear to work together to cause or precipitate depressive disorders. Interactions between important factors such as individual's sex, gender identity, race, ethnicity, culture, social status, genetics, environment, is at the heart of understanding the role of intersectionality on the etiology of depression.

PATHOPHYSIOLOGY

The monoamine hypothesis that depression is caused by decreased brain levels of serotonin (5-HT), dopamine (DA), and norepinephrine (NE) has been supported for over 50 years. However, the actual chemical basis for depression remains elusive.[13] This biogenic amine hypothesis evolved as a result of several observations made in the early 1950s that the antihypertensive medication reserpine depleted neuronal storage of NE, 5-HT, and DA and produced clinically significant depression in 15% or more of patients.[14] Subsequently, the hypothesis was supported by the mechanism(s) of antidepressant medications. Additionally, recurrence of depression has been induced by acute depletion of tryptophan (precursor of 5-HT) and 5-HT metabolite levels in cerebrospinal fluid are lower in some patients with MDD.[15] Evidence reveals the complexities of the monoamine systems in the brain. These systems are mediated by gamma aminobutyric acid (GABA), neuroactive steroids, endogenous opioids, and nutritional imbalances.[16–22] For the purposes of this chapter, the focus of medication mechanism of action will be the monoamine hypothesis unless otherwise specified (Figs. 88-1 and 88-2).

FIGURE 88-1

Monoamine neurotransmitter (NT) regulation at the neuronal level. NTs carry messages between cells. Each NT generally binds to a specific receptor, and this coupling initiates a cascade of events. NTs are reabsorbed back into nerve cells by reuptake pumps (ie, transporter molecules) at which point they may be recycled for later use or broken down by enzymes. For their primary mechanism of action, most antidepressants are thought to inhibit the transporter molecules and allow more NT to remain in the synapse. *(Reprinted from Mind Over Matter: The Brain's Response to Drugs - Teacher's Guide Revision. Monoamine systems do not function independently, but serve as feedback mechanisms for each other. Therefore, a medication that preferentially enhances NE transmission may secondarily alter both 5-HT and DA activity.[23,24]

Although increases in synaptic monoamines (eg, NE, DA, and 5-HT) occurs rapidly after initiation of an antidepressant, the clinical effects (ie, measurable symptom improvement) are generally delayed by weeks.[15,23] This delay may be the result of a cascade of events from receptor occupancy to gene transcription, downregulation of presynaptic feedback mechanisms, secondary effects on other neurotransmitter symptoms or neuroplasticity.[13,15,25] This led researchers to focus on the adaptive changes induced by antidepressants. In the mid-1970s, chronic, but not acute, administration of antidepressants to animals caused desensitization of NE-stimulated cyclic adenosine monophosphate synthesis. In fact, for most antidepressants, downregulation of β-adrenergic receptors accompanies this desensitization.[26,27] Studies of many antidepressants have demonstrated that either desensitization or downregulation of NE receptors corresponds the time course for antidepressant effects.[27] Other studies have revealed desensitization of presynaptic 5-HT$_{1A}$ autoreceptors following chronic administration of antidepressants.[15] These theories based on changes in receptor sensitivity provide a cogent explanation for the delayed onset of therapeutic response with antidepressant medications. The dysregulation hypothesis incorporates the diversity of antidepressant activity with the adaptive changes occurring in receptor sensitization over several weeks. In this theory, emphasis is placed on a failure of homeostatic regulation of NT systems rather than on absolute increases or decreases in their activities. According to this hypothesis, effective antidepressant agents restore efficient regulation to the dysregulated NT system.[13]

Traditional explanations of the biologic basis of depressive disorders have focused largely on NE and 5-HT. However, most of the evidence that coalesced into the biogenic amine hypothesis of depression does not clearly distinguish between NE and DA. There is an abundance of evidence suggesting that DA transmission is decreased in depression, and agents that increase dopaminergic transmission have been found to be effective antidepressants.[23] Specifically, increased DA transmission in the mesolimbic pathway accounts for at least part of the mechanism of action of antidepressant medications.[23] The mechanisms by which antidepressant medications alter DA transmission remain unclear, but may be mediated either directly by dopaminergic changes or indirectly by primary actions at NE or 5-HT terminals. The complexity of the interaction between 5-HT, NE, and DA is gaining greater appreciation, but a more in-depth understanding of the precise mechanism is needed. The availability of dopaminergic-based first-line and augmentation antidepressant strategies (eg, bupropion, high-dose venlafaxine, second-generation antipsychotics) may help answer remaining questions.

Neuroactive steroids are a growing area of research in depression as a link between the progesterone metabolite, allopregnanolone and depression has been found. Allopregnanolone release is increased in the setting of acute stress and may serve a neuroprotective role. However, with chronic stress and MDD central nervous system (CNS) concentrations of allopregnanolone may decrease. Rapid decline in allopregnanolone levels in the postpartum period have been associated with postpartum depression.[28] Furthermore, certain antidepressants have been shown to increase cerebral spinal fluid (CSF) levels of allopregnanolone proportional to depressive symptom response.[18]

Another proposed pathway for depression involves a complex interplay of inflammation and overexcitation resulting in decreased neuroplasticity and neuronal differentiation. Brain-derived neurotrophic factor (BDNF) is a primary mediator of these neuronal changes as well as synaptogenesis. Chronic stress, associated with increased glucocorticoids such as cortisol, may lead to decreased BDNF expression. Evidence suggests this process may be prevented, or possibly even reversed, by antidepressant medications or electroconvulsive therapy (ECT).[29] Increased BDNF expression after treatment initiation follows timeline similar to antidepressant response.[29]

Chronic stress and inflammation also alter glutamate and GABA transmission, changes that have been linked to depression and decreased BDNF. Increased GABA$_A$ receptor activity is associated with decreased transmission of 5-HT and increased NE transmission while increased GABA$_B$ receptor activation is associated with decreased 5-HT and NE transmission.[24] Increased serum and extrasynaptic glutamate has been associated with MDD symptom severity. Many available antidepressants decrease serum glutamate concentrations and are thought to increase BDNF activity.[16,29] An example of this is ketamine which inhibits extrasynaptic NMDA receptors, theoretically increasing synaptic glutamate activity, triggering BDNF release from synaptic vesicles.[30] Further, BDNF has been shown to decrease expression of GABA$_A$ receptors possibly resulting in increased 5-HT and NE transmission linking it back to the monoamine hypothesis.[29] The interaction of all of these related systems is not fully understood. However, the complexities could partially explain differences in response to medications as there are likely distinct subtypes of depression with different pathogenesis.

Biologic Markers

Investigators continue to search for biologic markers to assist in the diagnosis and treatment of MDD. Although no gold-standard biologic marker has been discovered, several biologic abnormalities have been variably identified in patients with MDD. Hypersecretion of cortisol or a lack of cortisol suppression after dexamethasone administration (ie, a positive dexamethasone suppression test) has been positively correlated to depression as well as risk of suicide.[31] Although the widespread use of this test has fallen out of favor in recent decades (due to limited sensitivity and specificity), the inability of the brain to suppress the hypothalamic–pituitary–adrenal (HPA) axis and the associated stress response could contribute to depression, possibly due to excessive glutamate and decreased BDNF discussed above.[31] According to this theory, there is a disruption somewhere in the normal negative feedback system that controls cortisol levels.

FIGURE 88-2

The presynaptic regulation and post-synaptic actions of serotonin and norepinephrine is multifaceted and many of the steps have been implicated in the pathophysiology of depression. Currently available oral antidepressants have mechanisms focused on presynaptic regulation. Most first-line antidepressants target serotonin and/or norepinephrine transporters which are responsible for ‘reuptake’ of the neurotransmitters into pre-synaptic neurons (hence, selective serotonin reuptake inhibitors or serotonin and norepinephrine reuptake inhibitors). Polymorphisms in these transporters have been associated with depression and may impact efficacy of medications that target the transporters. Other medication targets include MAO, 5HT1A receptors (vilazodone, vortioxetine) and α2 receptors (mirtazapine). Due to the complexity of these systems, there are numerous other targets at various stages of investigation. *(*Reproduced, with permission, from DeBattista C. Antidepressant Agents. Katzung BG, ed. Emerging evidence provides promise for both biologic and genetic markers for MDD. As previously mentioned serum levels of glutamate have correlated with MDD severity and rising concentrations of BDNF in the CNS have correlated to antidepressant response. The genes coding for BDNF production have been identified with polymorphisms that result in lower levels of BDNF.[29] Another focus of pharmacogenomics has been on polymorphisms of methylenetetrahydrofolate reductase (*MTHFR*) as they relate to differences in rates of depression and antidepressant response (inconsistent results to date).[32] Multiple other phenotypes have been identified and are available for testing with commercially available products, but evidence to date does not support routine testing for diagnosis or to predict treatment response.[33] Nor is there enough evidence to support testing CNS concentrations of BDNF or serum concentrations of glutamate.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Depressive Disorder

Emotional Symptoms

- Diminished ability to experience pleasure
- Loss of interest and pleasure in usual activities, hobbies, or work (anhedonia)
- Pessimism, hopelessness regarding feeling better
- Anxiety
- Voices (eg, auditory hallucinations) saying negative comments or suggesting suicide

Physical Symptoms

- Chronic fatigue resulting in decreased ability to attend to daily tasks (eg, bathing, grooming)
- Fatigue does not improve with rest and is often associated with pain, headache
- Changes in sleep (eg, early morning awakening, difficulty falling asleep, frequent awakening or increased sleep with associated fatigue)[34]
- Appetite changes (eg, most common decreased appetite and unintentional weight loss; increased appetite/weight gain atypical)[34,35]
- Gastrointestinal disturbances, genitourinary issues, cardiovascular complaints (eg, palpitations), loss of libido

Cognitive Symptoms[35]

- Decreased concentration or slowed thinking
- Poor memory for recent events (especially older adults)
- Confused or indecisive

Psychomotor Disturbances

- Slow physical movements, speech and thought processes (psychomotor retardation)
- Restlessness (eg, pacing, wringing of hands), outbursts of anxiety or agitation (eg, crying or yelling); together known as psychomotor agitation

② When a patient presents with depressive symptoms, it is necessary to investigate the possibility of a contributing medical or medication-induced etiology. All patients evaluated for depression should have a complete physical examination, mental status examination, and basic laboratory workup, including a complete blood count (CBC) with differential, thyroid function tests, and electrolytes, to identify any potential medical problems. While a complete discussion of medical conditions associated with depression is beyond the scope of this chapter, multiple common medical conditions are associated with development of depressive symptoms, such as stroke, Parkinson disease, traumatic brain injury, and hypothyroidism. Other conditions associated with increased risk for depression include pain, diabetes, seizures, and coronary artery disease.[36] The *DSM-5* describes a diagnostic category for both "Depressive Disorder Due to Another Medical Condition" and "Substance/Medication-Induced Depressive Disorder,"[1] which emphasizes the importance of ruling out alternative causes of symptoms. A complete medication review should include both current and previous medications to assess for both helpful and contributing medications. Additionally, consider the contribution of substance withdrawal (eg, cocaine, cannabis, or alcohol) to depressive symptoms. Table 88-1 lists medications commonly associated with causing or exacerbating depressive symptoms.[37–44]

Once other medical, medication or substance related causes of symptoms have been ruled out, the patient should be evaluated for MDD. According to the *DSM-5*, a single major depressive episode is characterized by five (or more) of the symptoms described in Table 88-2.[1] At least one of the symptoms is depressed mood (often an irritable mood in children or adolescents) or loss of interest or pleasure in nearly all activities.[1] These symptoms must have been present nearly every day for at least 2 weeks and must represent a change from the patient's previous level of functioning. The diagnostic code for MDD is determined by whether this is a single or recurrent depressive episode, current severity, presence of psychotic features, and remission status. The diagnosis can be followed by specifiers that apply to the current episode. The possible specifiers include anxious distress, mixed features (ie, presence of manic/hypomanic features), melancholic features, atypical features, mood-congruent or incongruent psychotic features, catatonia, peripartum onset, and seasonal pattern. The clinician must consider presenting symptoms, their duration, and the patient's current level of social, occupational, or other important areas of functioning. Significant stressors or life events may trigger depression in some individuals; however, not all patients will have a clear precipitant.[1]

TABLE 88-1

Select Medications Associated with Depressive Symptoms

Medication class	Individual agents	Comments
Acne treatment	Isotretinoin	• REMS program iPledge recommends monitoring psychiatric symptoms
Antiseizure medications	All FDA-approved antiseizure medications (including clorazepate and clonazepam)	• Specific warning added to labeling under Warnings and Precautions regarding increased risk of suicidal thoughts or behavior • Not all agents with warning have demonstrated increased risk • Controversial
Cardiovascular medications	Reserpine	• Rarely used due to historical reports of depression due to depletion of monoamines
	Angiotensin receptor blockers β-blockers Calcium channel blockers Clonidine Methyldopa	• Conflicting data for most agents • β-blockers classically linked to depression; however, most evidence supports only physical symptoms of fatigue and low energy • Link between cardiovascular disease and depression must be considered
Central nervous system agents	Deutetrabenazine Tetrabenazine Valbenazine	• Deplete synaptic monoamines via decreasing vesicular transport in presynaptic neurons • Deutetrabenazine and tetrabenazine have boxed warning for depression and suicidality
Hormonal therapy	Gonadotropin-releasing hormone Oral contraceptives	• Linked to alterations in progesterone and estrogens and possible link to monoamine oxidase activity
	Steroids (eg, prednisone)	• Possible association with inflammation and HPA axis changes in depression
Immunologic agents	Interferons	• Labeled warning
Smoking cessation medications	Varenicline	• Reports to FDA MedWatch after release • Large postmarketing study does not support increased risk

REMS, Risk Evaluation and Mitigation Strategy; FDA, Food and Drug Administration.

Data from References [2,37–44].

TABLE 88-2

Diagnostic Criteria for Major Depressive Episode

S	Suicidal ideation with or without plan, suicide attempt; recurrent thoughts of death
I	Interest—loss of interest or pleasure in activities; anhedonia
G	Guilt—inappropriate or excessive in nature; feelings of worthlessness
E	Energy decreased
C	Concentration decreased; difficulty making decisions
A	Appetite changes; typically decreased; resulting in 5% change in weight from baseline
P	Psychomotor agitation or retardation
S	Sleep impairment; typically insomnia but may be hypersomnia

- At least five symptoms must be consistently present over a 2-week period.
- Symptoms must include depressed mood or anhedonia.
- Symptoms must cause substantial distress or impairment in functioning.
- Other medical conditions or substance use do not account for symptoms.

Data from Reference [1].

Depression Rating Scales

Instruments to assess the severity of depressive symptoms can be used for both clinical and research purposes. For example, the Montgomery-Åsberg Depression Rating Scale (MADRS) is a clinician-administered scale that is commonly used in clinical trials given its sensitivity to change.[45] Some depression rating scales are self-administered such as the Beck Depression Inventory (BDI) that takes only 5 to 10 minutes to complete by the respondent.[46] The PHQ-9 is another brief scale that has been validated for use.[47] For a more detailed explanation of these instruments, as well as other rating scales and evaluation approaches, refer to Chapter e81.

Emotional Symptoms

A major depressive episode is characterized by a persistent, diminished ability to experience pleasure, and as such a loss of interest and pleasure in usual activities, hobbies, or work is common. Patients appear sad or depressed, and they are often pessimistic and believe that nothing will help them feel better. The occurrence of guilty feelings that are unrealistic is common, and these may reach delusional levels where patients feel that they deserve punishment and may view their present illness as a punishment. A patient suffering from MDD with psychotic features may hear voices, usually auditory hallucinations saying that they are a bad person or should try to die by suicide. Depression with psychotic features may require hospitalization, especially if the patient becomes a danger to self or others. Additionally, anxiety symptoms are present in almost 90% of outpatients with depression, which may have treatment implications.

Additional Symptoms of Depression

Physical symptoms, rather than emotional symptoms, often motivate patients, especially older adults, to seek medical attention. Chronic fatigue, with a decreased ability to perform normal daily tasks is a common presenting symptom. The fatigue seen in patients with depression often appears worse in the morning, does not improve with rest, and is frequently accompanied by pain, especially headache.

Sleep disturbances generally present as early morning awakening with difficulty returning to sleep. This may coexist with difficulty falling asleep and frequent nighttime awakening, daytime exhaustion or fatigue. Hypersomnia (increased sleep) is less common. Recognition and management of sleep disturbances among patients with depression is crucial, as approximately 60% to 90% of patients experiencing MDD report sleep disturbances.[34]

Appetite disturbances, specifically decreased appetite, often result in substantial weight loss, especially in older adults.[34,35] Some patients lose 2 lb (0.9 kg) or more per week without dieting. Other patients may overeat and gain weight, although they typically do not enjoy eating.

Patients may present with a variety of other symptoms such as gastrointestinal (GI) issues (eg, pain, nausea, diarrhea, constipation), genitourinary issues (eg, incontinence, pain), cardiovascular complaints (eg, palpitations), cognitive impairment (especially older adults), or muscle fatigue. Lastly, patients frequently present with a loss of sexual interest or libido.

In addition to physical symptoms patients with MDD frequently experience cognitive and psychomotor disturbances noted in the Clinical Presentation box.

Suicide Risk Evaluation and Management

As of 2018, the Centers for Disease Control and Prevention listed death by suicide as the tenth leading cause of death among Americans and the second leading cause of death among 10- to 44-year-olds.[6] Suicide rates increased between 6% and 58% in 49 of 50 states between 1999 and 2016 and the rates in adolescents in particular are rising in the face of the COVID pandemic.[8,48] All patients diagnosed with MDD should be assessed for suicidal thoughts and factors associated with increased risk for suicide including other psychiatric disorders, substance use disorders, adolescents and younger adults, physical illness, recent stressful life event, childhood trauma, hopelessness, and male gender.[49] Those with a higher level of risk often have high degree of suicidal intent and describe more specific plans, in particular, plans that are violent and irreversible.[49] The risk of death by suicide in those recovering from MDD may increase as they develop the energy and capacity to act on a plan made earlier in a course of illness. Despite factors to help identify those at greatest risk, it remains very difficult to predict suicidality in any given individual. Therefore, when suicidal intent is suspected, it is important to ask, “Are you thinking about harming or killing yourself?” (See Chapter e81 for more information.) If the risk is significant, the patient must be referred immediately to an appropriate healthcare professional. Certain depression rating scales, such as the MADRS and PHQ-9 discussed above, include questions that target suicidality, which may help identify those patients at risk. Additionally, the Columbia-Suicide Severity Rating Scale is widely accepted in clinical practice as a validated assessment of suicide risk.[50]

In September 2004, the FDA required manufacturers of antidepressants to add a boxed warning stating that all antidepressants increase the risk of suicidal thinking and behavior in short-term studies in children and adolescents with depressive disorders. These risks have become a new source of concern among those treating their patients with antidepressants. In order to help deal with the confusion these warnings have caused, experts have recommended the following:[51]

1. It is especially important to closely monitor patients for suicidal ideation and behavior at the beginning of treatment and among younger patients.
2. Discuss the possibility that adverse medication reactions may occur, including behavioral agitation or anger, and encourage patients to seek help should this occur.
3. Deal with the subject of suicide directly.

Withholding antidepressant treatment may decrease the risk of suicide and may actually increase the risk. Furthermore, it may be that longer-term medication is needed for any protective effects against suicidality.[51]

In May 2007, the FDA expanded the boxed warning regarding suicidality to include young adults 18 to 24 years of age, during the initial stages of treatment. The warning also applies to any medication with either monotherapy or adjunct treatment of depression as an FDA-approved indication even if not classified as an “antidepressant” (eg, aripiprazole, quetiapine).

Assessment of actual suicide risk has proven to be difficult as there are differences in coding of events in clinical trials and complete case data from trials is often not available. Additionally, there appears to be an increased risk of suicidality in the 30 days after antidepressant discontinuation, which is not routinely evaluated in clinical trials.[52] An increased risk of suicidality in children and adolescents has been found in multiple studies and this population should be evaluated carefully upon initiation or discontinuation of antidepressant treatment. The complex relationships between antidepressant use and suicidality will continue to be explored with the hopes of more unequivocal recommendations.

TREATMENT

Desired Outcomes

③ The goal of treating depression is resolution of depressive symptoms and return to previous level functioning. Initial treatment may occur in the hospital or in outpatient treatment settings. Hospitalization is more likely when there is a high risk of suicide, poor physical health, limited social support or psychotic symptoms. Response, typically defined as 50% decrease in symptoms and is achieved in 40% to 50% of patients 8 to 12 weeks after medication initiation. Remission (absence of symptoms) is achieved in 25% to 30% of patients within 8 to 12 weeks after medication initiation.[3]

General Approach to Treatment

There are three treatment phases for patients with MDD: (a) the *acute* phase lasting approximately 6 to 12 weeks in which the goal is remission; (b) the *continuation* phase lasting 4 to 9 months after remission is achieved, in which the goal is to eliminate residual symptoms or prevent relapse (ie, return of symptoms within 6 months of remission); and (c) the *maintenance* phase lasting at least 12 to 36 months in which the goal is to prevent recurrence (ie, a separate episode of depression).[2,53] The duration of antidepressant therapy depends on the risk of recurrence which increases with each depressive episode. Some guidelines recommend lifelong maintenance therapy for persons at greatest risk for recurrence (younger than 40 years of age with two or more prior episodes or any age with three or more prior episodes).[2] An alternative guideline is to treat for at least 2 years in patients at high risk for relapse.[3] The decision to taper/discontinue an antidepressant regimen is always going to depend on patient- and medication-specific variables. Both SSRIs and SNRIs have an idiosyncratic discontinuation syndrome and should be slowly tapered over weeks to months to minimize risk. However, a slow taper is not always effective in preventing discontinuation symptoms.[54]

④ Educating the patient and their support system (eg, family and friends) regarding the delay in antidepressant effects and the importance of medication adherence should occur before and during the entire course of treatment. The treatment of MDD generally includes both nonpharmacologic and pharmacologic strategies.

Nonpharmacologic Therapy

In addition to pharmacologic interventions, psychotherapy ("talk therapy") should be employed whenever the patient is able and willing to participate. Traditionally, psychotherapy alone is recommended only for mild to moderately severe cases of MDD. However, evidence supports the benefit of cognitive behavioral therapy (CBT) for even severe MDD.[55] Psychotherapy should not be the primary treatment modality for patients with psychotic features. The effects of psychotherapy and antidepressant medications are considered to be additive, thus combined treatment may be advantageous for patients with partial responses to either treatment alone and for those with a chronic course of illness. In practice, CBT as primary treatment is limited significantly by cost and logistics (eg, need for more frequent appointments and time off work). Additionally, many insurance plans do not adequately cover the cost of psychotherapy, the availability of providers may be limited in certain areas, and patients may be more reluctant to spend the time in therapy versus taking medication. In the Sequenced Treatment Alternatives to Relieve Depression study (STAR*D), evaluation of the psychotherapy arm was limited by low participation rates.[56]

Electroconvulsive therapy (ECT) is a safe and effective treatment for severe MDD. Ideally it is used when a rapid response is needed (eg, severe suicidality, nutritional deficiency, catatonic symptoms), risks of other treatments outweigh potential benefits, symptoms refractory to two antidepressant trials, or there is history of good response to ECT, and the patient expresses a preference for ECT. Another nonpharmacologic approach is repetitive transcranial magnetic stimulation (rTMS), which has demonstrated efficacy in treating MDD symptoms without the anesthesia required for ECT.[57]

The health benefits of physical activity have long been recognized for many medical conditions, and data suggest benefits in depressed patients. The Treatment with Exercise Augmentation for Depression (TREAD) study demonstrated that 16 kcal (67 kJ) per kilogram per week (KKW) exercise was associated with greater MDD remission rates compared with 4 KKW, when both were used as augmentation to an SSRI.[58] According to APA taskforce integrating exercise into the MDD treatment plan is medically appropriate and confers many well-accepted health benefits.[59]

Pharmacologic Therapy

Antidepressants are considered first-line treatment for a moderate-to-severe depressive episode.[2–4] They can be classified in several ways, including by chemical structure and the presumed mechanism of antidepressant activity. Although the link between the presumed mechanism of action and antidepressant response is tenuous, this classification has the advantage of being based on established pharmacology and clearly explains some of the common, but expected, adverse medication reactions. The knowledgeable clinician can use these antidepressant properties to tailor treatment to individual patient needs and optimizing treatment outcome. Currently available antidepressants, including dosing guidance, are provided in Table 88-3.[2,3,53,60–62]

TABLE 88-3

Adult Dosing Guidance for Currently Available Antidepressant Medications

Medication (Brand Name)	Initial Dose (mg/day)	Usual Dosage Range (mg/day)	Comments (eg, Maximum Daily Dosage, Suggested Therapeutic Plasma Concentration)
Selective Serotonin Reuptake Inhibitors (SSRIs) Patients with significant anxiety should start with lower initial dose to improve tolerability; however, target dose does not differ.			
Citalopram (Celexa)	10-20	20-40	Doses >40 mg/day not recommended due to QTc prolongation risk; maximum 20 mg/day for CYP2C19 poor metabolizers, coadministration with CYP2C19 inhibitors or patients older than 60 years of age
Escitalopram (Lexapro)	5-10	10-20	Maximum 20 mg/day; dose may be increased to maximum daily dose after 1 week
Fluoxetine (Prozac)	10-20	20-60	Maximum 80 mg/day; dose may be increased in 20-mg increments
Fluvoxamine (Luvox)	25-50	50-300	Maximum 300 mg/day; daily doses >100-mg total dose should be divided twice daily, with the larger dose given at night Maximum 300 mg/day (ER formulation)
Paroxetine (Paxil)	10-20	20-50	Maximum 50 mg/day (IR formulation); titrate 10 mg/day increments weekly Maximum 62.5 mg/day (CR formulation); titrate 12.5 mg/day increments weekly
Sertraline (Zoloft)	25-50	50-200	Maximum 200 mg/day; titrate 25 mg/day increments weekly
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)			
Newer-generation SNRIs			

Desvenlafaxine (Pristiq)	50	100	Doses up to 400 mg/day have been studied; however, tolerability decreases with doses >50 mg. Dose reductions or discontinuation may be required if sustained hypertension occurs
Duloxetine (Cymbalta)	30	30-90	Maximum 120 mg/day (given once or twice daily); doses >60 mg/day not shown to provide increased efficacy for the treatment of MDD
Venlafaxine (Effexor)	37.5-75	75-225	Maximum 375 mg/day (IR); maximum 225 mg/day (ER); may increase in increments up to 75 mg/day at a minimum of every 4 days. Dose reductions or discontinuation may be required if sustained hypertension occurs
Levomilnacipran (Fetzima)	20	40-120	Initial dose (20 mg) for 2 days before dose increases is recommended at intervals of two or more days. Dose adjustment or discontinuation may be required if sustained elevated heart rate or hypertension occurs
Tricyclic antidepressants (TCAs)			
Amitriptyline (Elavil)	25	100-200	Maximum 300 mg/day for MDD; as single daily dose at bedtime or divided doses; therapeutic serum level 80-200 ng/mL (mcg/L;~300-740 nmol/L); parent medication plus metabolite (nortriptyline)
Desipramine (Norpramin)	25	100-200	Maximum 300 mg/day; suggested therapeutic concentration range for combined imipramine + desipramine: 100-300 ng/mL (mcg/L; ~370-1,100 nmol/L)
Doxepin (Sinequan)	25	100-200	Maximum 300 mg/day as a single daily dose at bedtime (if tolerated) or in divided doses; a single dose should not exceed 150 mg
Imipramine (Tofranil)	25	100-200	Maximum 300 mg/day as single daily dose at bedtime (if tolerated) or divided doses; suggested therapeutic concentration range for combined imipramine + desipramine: 150-300 ng/mL (mcg/L;~550-1,100 nmol/L)
Nortriptyline (Pamelor)	25	50-150	Maximum 150 mg/day as single daily dose (if tolerated) or divided doses; therapeutic serum level 50-150 ng/mL (mcg/L;190-570 nmol/L)
Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)			
Bupropion (Wellbutrin)	150 (75 mg given twice daily)	150-450	Maximum 450 mg/day (IR, ER), 400 mg/day (SR); ER dosed once daily; SR dosed once or twice daily; IR may be dosed up to three times daily. Adhering to labeled maximum daily and maximum single doses minimizes effect on seizure threshold
Mixed Serotonergic Effects (Mixed 5-HT)			
Nefazodone	100	200-	Maximum 600 mg/day; daily doses should be divided twice daily; boxed warning

(Serzone)		400	hepatotoxicity
Trazodone (Desyrel)	50	150-300	Maximum 600 mg/day
Vilazodone (Viibryd)	10	20-40	Target dose 20-40 mg/day unless coadministered with CYP3A4 inhibitor (dose not to exceed 20 mg/day). Dose titration: 10 mg/day for 7 days, 20 mg/day for 7 days, and then may increase to 40 mg/day. Dose must be taken with food to ensure adequate absorption
Vortioxetine (Trintellix)	10	20	Maximum 20 mg/day
Serotonin and α_2-Adrenergic Antagonist			
Mirtazapine (Remeron)	15	15-45	Maximum 45 mg/day
Monoamine Oxidase Inhibitors (MAOIs)			
Phenelzine (Nardil)	15	30-90	Maximum 90 mg/day; divided dosing; increase by 15 mg at 1- to 3-week intervals
Selegiline (transdermal) (Emsam)	6	6-12	Not to exceed 12 mg/24 hours; dose may be increased by 3 mg/day increments every 2 weeks; site of application should be rotated
Tranylcypromine (Parnate)	10 10-20	20-40 30-60	Maximum 60 mg/day; divided dosing; increase by 10 mg at 1- to 3-week intervals
Isocarboxazid (Marplan)	10-20	30-60	Maximum 60 mg/day; divided dosing
Second-generation Antipsychotics (SGA) as Augmentation (5HT$_{2A}$ and D$_2$ modulators)			
Aripiprazole (Abilify)	2	2-15	FDA approved for augmentation; CANMAT Level 1 evidence, 1st line
Brexpiprazole (Rexulti)	1	1-3	Not FDA approved for augmentation; CANMAT Level 1 evidence, 2nd line
Olanzapine (Zyprexa)	2.5	2.5-10	Not FDA approved for augmentation; CANMAT Level 1 evidence, 2nd line

Olanzapine/fluoxetine (Symbyax)	3/25	6-12/25-50	FDA approved for treatment-resistant depression
Quetiapine (Seroquel)	50	150-300	FDA approved for augmentation; CANMAT Level 1 evidence, 1st line
Risperidone (Risperdal)	1	1-3	Not FDA approved for augmentation; CANMAT Level 1 evidence, 1st line
Alternative Augmentation Agents (Not FDA Approved for Antidepressant Augmentation)			
Buspirone (Buspar)	10	10-60	Divided dosing 2 to 3 times daily 5HT1A partial agonist
Lithium	300	600-1200	Dose based on therapeutic levels (target 0.6-1 mEq/L [mmol/L]) Mechanism in depression not fully understood
Triiodothyronine (Cytomel)	0.025	0.025-0.05	Once daily dosing; monitor free T3 levels

CANMAT, Canadian Network for Mood and Anxiety Treatments; CR, continuous release; ER, extended release; IR, immediate release; MDD, major depressive disorder; SR, sustained release.

Data from References [2,3,53,60,61], *and* [62].

⑤ Antidepressants are of *equivalent efficacy* when administered in comparable doses. Because one cannot predict which antidepressant will be the most effective in an individual patient, the initial choice is made empirically. Factors that often influence antidepressant choice include the patient's history of response, history of familial antidepressant response, concurrent medical illnesses and medications, presenting symptoms (eg, insomnia vs hypersomnia), potential for medication interactions, adverse medication reactions, patient preference, and medication cost. Although the precise pathophysiology of MDD remains elusive, clinicians can now select from multiple approved medications with different mechanisms of action (Tables 88-3 and 88-8).[2–4,63] Failure to respond to one antidepressant class or one antidepressant agent within a class does not predict a failed response to another class or another agent within the same class (Fig. 88-3). Approximately 50% to 60% of patients with MDD improve with acute medication therapy, compared with about 30% to 40% who improve with placebo.[3,64]

TABLE 88-4

Relative Potencies of Norepinephrine and Serotonin Reuptake Blockade and Select Receptor Antagonism Profile of Antidepressants

	Reuptake Antagonism		M1	H1	α1
	NE	5-HT			
Selective Serotonin Reuptake Inhibitors (SSRIs)					
Citalopram	0	++++	0	+	0
Escitalopram	0	++++	0	0	0

Fluoxetine	+	++++	0	0	0
Fluvoxamine	0	++++	0	0	0
Paroxetine	++	++++	++	+	0
Sertraline	0	++++	0	0	+
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)					
Duloxetine	+++	++++	0	0	0
Levomilnacipran	++++	+++	+	0	0
Venlafaxine[a] and desvenlafaxine	+++	++++	0	0	0
Tricyclic Antidepressants (TCAs)					
Amitriptyline	++	++++	++++	++++	+++

Vortioxetine	0	++++	0	+	0
Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)					
Bupropion[b]	+	0	+	0	0
Serotonin and α_2-Receptor Antagonist					
Mirtazapine	0	0	0	+++	+

M1, antimuscarinic/anticholinergic adverse reactions; H1, antihistamine, sedation; α1 antiadrenergic, hypotension.

++++, high; +++, moderate; ++, low; +, very low; 0, absent or not adequately studied.

[a] Venlafaxine: primarily 5-HT at lower doses, NE at higher doses, and DA at very high doses.

[b]Bupropion: also blocks dopamine reuptake.

Data from References 2–4,53, and 63.

Selective Serotonin Reuptake Inhibitors

The efficacy of SSRIs is superior to placebo and comparable to other antidepressant classes in treating patients with MDD.[2,53] They are generally chosen as *first-line* due to relative safety in overdose and improved tolerability over TCAs and MAOIs. The decision of which SSRI to use is typically based on the nuances of each medication, such as differences in interaction profile and pharmacokinetic (PK) parameters (eg, half-life). These concepts will be discussed in greater detail later in this chapter. The STAR*D trial demonstrated that nonresponse to one SSRI does not predict nonresponse to an alternative SSRI and a recent meta-analysis found no differences in efficacy between agents.[56,65]

The SSRIs, as the name implies, have a low affinity for other receptors including alpha$_1$-adrenergic (α1), histaminic (H1), and muscarinic (M1) receptors. Given this pharmacology, they are associated with lower rates of orthostatic hypotension, sedation, weight gain, and anticholinergic effects compared to TCAs.[2–4,63] The most common dose-dependent tolerability issues with SSRI use, which generally are mild and limited to 1 to 2 weeks after initiation or dose increases, are GI symptoms (eg, nausea, vomiting, and diarrhea), anxiety, and headache.[66] Both somnolence and insomnia have been reported with all SSRIs.[67] Additionally the SSRIs may cause clinically relevant impairment in all three stages of the human sexual response (arousal, libido, orgasm)[68]; however, it is important to note that depression itself may be associated with sexual dysfunction. A discontinuation or withdrawal syndrome may occur if SSRIs are abruptly discontinued (see details below with SNRIs). Paroxetine has more anticholinergic and antihistaminergic activity that has been linked with increased sedation and weight gain compared to other SSRIs.[2–4,63] The FDA released a safety announcement linking citalopram to a dose-dependent increase in QT interval, with recommended, age-dependent dose limits.[69] There has since been controversy regarding this safety warning and potential unintended consequences (eg, underdosing, discontinuation leading to relapse).[69,70] Dose-dependent increase in QT interval may also be associated with escitalopram; however, clinical significance of the QT increase is questionable with both agents.[69]

Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)

Tricyclic Antidepressants

Although TCAs are effective in treating MDD, use has diminished greatly due to the availability of equally effective therapies that are better tolerated and much safer in overdose. All TCAs potentiate the activity of NE and 5-HT by blocking their reuptake. However, the potency and selectivity of TCAs for the inhibition of NE and 5-HT reuptake vary greatly among these agents (see Table 88-8). Nortriptyline is most commonly used and may be selected in patients with comorbid migraine headaches, neuropathic pain, or fibromyalgia.

The TCAs affect other neurotransmitters and produce a wide range of pharmacologic actions, including several unwanted, but expected, adverse medication reactions. The most commonly occurring dose-related adverse reactions are anticholinergic in nature and include dry mouth, constipation, blurred vision, urinary retention, dizziness, and tachycardia (see Table 88-8). In older adult patients or with very high doses, memory impairment or delirium may occur.[71] Although some tolerance does develop, these reactions have the potential to impact patient adherence, particularly in older adults and those receiving long-term maintenance therapy. Additional tolerability issues that decrease TCA adherence include weight gain and sexual dysfunction.[71]

Orthostatic hypotension is a common, dose-related reaction attributed to the affinity of the TCAs for α_1 receptors.[63] In patients with history of myocardial infarction, TCAs should be avoided due to risk of severe arrhythmias (QTc prolongation, torsades de pointes) thought to be associated with their class IA antiarrhythmic effects.[72] Additionally, TCAs can cause cardiac conduction delays, may induce heart block in patients with a preexisting conduction disorder, and overdose is associated with severe arrhythmias.[71] Desipramine's prescribing information reflects an increased risk of death in patients receiving the medication who have a *family history* of sudden cardiac death, cardiac dysrhythmias, and cardiac conduction disturbances. More on this reaction can be found at the FDA's MedWatch Website. Caution should be exercised when prescribing these agents, especially in higher doses, to patients with clinically significant cardiac disease, and to patients with a family history of a cardiac event.

Newer-Generation SNRIs

Venlafaxine and its primary active metabolite, desvenlafaxine, inhibit 5-HT reuptake at low doses, and NE reuptake at higher doses, whereas duloxetine equally inhibits both 5-HT and NE reuptake inhibition across all doses. This difference in receptor binding has not been associated with significant differences in efficacy. According to some studies the SNRIs may be associated with higher rates of response and remission than other antidepressants; however, most of these studies involved venlafaxine, and not all studies support this conclusion.[65] The BAP guidelines discuss the possibility of a slight efficacy advantage (ie, lower number needed to treat; NNT) for venlafaxine (as well as escitalopram and sertraline) compared to other antidepressants.[3]

The most recent SNRI to be FDA-approved for MDD is levomilnacipran. This is a single-isomer, extended-release formulation of milnacipran which is FDA-approved only for the treatment of fibromyalgia. It is too soon to determine its place in therapy for MDD; however, pharmacologically it is relatively unique among the SNRIs given its greater potency at inhibiting NE reuptake compared to 5-HT reuptake.[63,73] One NE selective reuptake inhibitor, reboxetine, available in non-US markets, was not FDA approved due to poor tolerability and lack of efficacy.

The most commonly reported tolerability issues with SNRIs, similar to those of SSRIs, may be dose-related and include nausea, sexual dysfunction, and activation.[2–4] Hyperhidrosis (excessive sweating) occurs primarily with SNRIs. Dose-related increases in blood pressure have been reported more with venlafaxine and levomilnacipran but may also occur with duloxetine and desvenlafaxine.[2] Blood pressure should be monitored at baseline and regularly during therapy, especially after dose increases. The discontinuation or withdrawal syndrome that can occur when treatment is stopped, appears to be more severe with SNRIs than SSRIs. Common withdrawal symptoms include headache, fatigue, sweating, musculoskeletal pain, electric shock sensations, and anxiety. While slowly tapering off the medication may help to reduce the risk of the withdrawal syndrome, it may not fully prevent.[54] Duloxetine has also been associated with idiosyncratic hepatotoxicity (1 per 100,000 case exposures) with enzyme elevations more than three times upper limit of normal in 1% of patients, but does not carry the boxed warning associated with nefazodone.[74]

Mixed Serotonergic Medications (Mixed 5-HT)

Trazodone and nefazodone have dual actions on serotonergic neurons, acting as both postsynaptic 5-HT$_2$ antagonists and presynaptic 5-HT reuptake inhibitors. They may also enhance 5-HT$_{1A}$-mediated neurotransmission.[63] Trazodone blocks α_1 and H1 receptors leading to adverse reactions (eg, dizziness and sedation) that limit its use as an antidepressant. Use of nefazodone declined after reports of hepatotoxicity and the FDA-approved labeling includes a boxed warning describing rare cases of fulminant liver failure (1 case per 300,000 treatment years) and hepatic impairment (29 cases per 100,000 treatment years).[74] Trazodone and nefazodone are effective agents in treating MDD; however, both carry risks that limit their usefulness. Immediate-release trazodone is most often used adjunctively (in low doses) with other antidepressants to treat insomnia associated with MDD.[67]

Trazodone and nefazodone have minimal anticholinergic effects and comparatively less 5-HT agonist adverse reactions (eg, sexual dysfunction), but they can cause orthostatic hypotension. Sedation, cognitive slowing, and dizziness are the most frequent dose-limiting adverse reactions associated with trazodone, although the dosage used for the treatment of depression is significantly higher than the dosage often used for the treatment of insomnia (25-200 mg).[4,67] Common adverse medication reactions associated with nefazodone include light-headedness, dizziness, orthostatic hypotension, and somnolence. Nefazodone treatment should not be initiated in individuals with active liver disease or with elevated baseline serum transaminases. A rare but potentially serious adverse reaction of trazodone is priapism, which is reported to occur in approximately 1 in 6,000 male patients. Some cases have required surgical intervention (1 in 23,000), and permanent impotence may result.[75] There have been no reports of priapism associated with nefazodone use in males, but there is a published case report of nefazodone-induced clitoral priapism.[75]

Vilazodone and vortioxetine are combination SSRI and 5-HT$_{1A}$ presynaptic receptor partial agonists approved for the treatment of MDD.[73] Presynaptic 5-HT$_{1A}$ partial agonism has previously been hypothesized as a mechanism for SSRIs augmentation with pindolol, which has preferential antagonism at the presynaptic 5-HT$_{1A}$ receptor.[76] The primary dose-limiting adverse reaction of these two newer agents is nausea. Vortioxetine additionally antagonizes 5-HT$_3$ which is proposed to mitigate some of the nausea, and is also a partial agonist at 5-HT$_{1B}$, and an antagonist at 5-HT$_{1D}$ and 5-HT$_7$ receptors.[62] Preliminary data support a linkage between the 5-HT$_7$ receptor antagonism and lack of cognitive slowing and potential for improved cognitive symptoms with vortioxetine in patients with MDD.

Vilazodone and vortioxetine are both associated with significant dose-related GI tolerability issues (eg, diarrhea and nausea), dizziness, insomnia, and decreased libido (particularly among males) when compared to placebo.[73] Rates of sexual dysfunction appear to be lower than with SSRIs; however, in some trials comparator agents known to cause sexual dysfunction (eg, duloxetine) also had lower rates of sexual dysfunction.[62,73]

Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)

Bupropion has no appreciable effect on the 5-HT reuptake, and inhibits both the NE and DA reuptake making it one of the most activating antidepressants.[63] This can be particularly helpful for decreased motivation, low energy, and fatigue, which are common symptoms in older adult patients. It is also FDA-approved for smoking cessation and in a combination product with naltrexone for weight loss.

Adverse medication reactions associated with bupropion include nausea, vomiting, tremor, insomnia, and dry mouth. The occurrence of seizures in patients taking bupropion appears to be strongly dose-related, and may be increased by predisposing factors such as history of prior seizure activity, severe alcohol withdrawal, head trauma, or CNS tumor. Bupropion use is contraindicated in patients with eating disorders such as bulimia and anorexia. In addition to risk for further appetite suppression, these patients are prone to electrolyte abnormalities and are therefore at higher risk for seizure activity. At daily doses of 450 mg (the FDA-approved maximum dose) or less, the incidence of seizures is 0.4%, which is similar to reported rates for clomipramine, desipramine, and citalopram.[77] Bupropion is associated with minimal sexual dysfunction compared with the SSRIs and may actually improve SSRI-induced sexual dysfunction when used as adjunctive treatment.[78]

Serotonin and α_2-Adrenergic Receptor Antagonists

Mirtazapine enhances central noradrenergic and serotonergic activity through the antagonism of central presynaptic α_2-adrenergic autoreceptors and heteroreceptors.[79] Furthermore, it antagonizes postsynaptic 5-HT_2, 5-HT_3, and H1 receptors resulting in anxiolytic, anti-nausea, and sedative effects, respectively.

The most common adverse medication reactions of mirtazapine are somnolence, weight gain (>7%), dry mouth, and constipation. Somnolence and weight gain in particular are likely due to relatively strong antihistaminergic properties.[67] Mirtazapine is associated with minimal sexual dysfunction.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors increase the concentrations of NE, 5-HT, and DA within the neuronal synapse through inhibition of the MAO enzymes. The MAOIs isocarboxazid, phenelzine, and tranylcypromine are nonselective inhibitors of MAO-A and MAO-B. A selegiline transdermal patch allows inhibition of MAO-A and MAO-B in the brain, yet has reduced effects on MAO-A in the gut.[80]

The most common adverse reaction of oral MAOIs is postural hypotension, which is more likely to occur with phenelzine and may be minimized with divided doses. Other common adverse reactions include weight gain and sexual dysfunction (eg, decreased libido and anorgasmia).[2] Phenelzine has mild-to-moderate sedating effects, while tranylcypromine and selegiline may exert a stimulating effect and insomnia due to amphetamine-like metabolites.[61]

Hypertensive crisis, which is a potentially serious and life-threatening but rare adverse reaction, may occur when MAOIs are taken concurrently with foods containing tyramine. Tyramine is usually metabolized by MAO-A in the gut and not absorbed into systemic circulation where it acts as a potent vasoconstrictor. Oral MAOIs block gut MAO-A resulting in absorption of tyramine. In patients on MAOIs, 10 mg of tyramine can cause marked hypertension and severe headache, and 25 mg can result in hypertensive crisis, whereas the average adult can tolerate over 500 mg of tyramine without a significant impact on blood pressure.[61,81] This may also occur when MAOIs are co-ingested with medications that increase norepinephrine (eg, decongestants, stimulants, SNRIs). Symptoms of hypertensive crisis include occipital headache, stiff neck, nausea, vomiting, sweating, and sharply elevated blood pressure which may culminate in cerebrovascular accident and death. For details regarding management of hypertensive emergencies, refer to Chapter 30, "Hypertension." The other significant risk of MAOIs is serotonin syndrome with concurrent use of other medications that increase serotonin (eg, antidepressants other than MAOIs). Education of patients taking MAOIs regarding dietary and medication restrictions is extremely important. Examples of potentially high tyramine foods and medications that should be avoided or used with caution are provided in Table 88-5.[61,81]

TABLE 88-5

Dietary and Medication Restrictions for Patients Taking Monoamine Oxidase Inhibitors[a]

Foods to Avoid Completely	Approximate Tyramine Content (mg) per Ounce
Aged cheeses (eg, cheddar, blue, Swiss, Camembert)	25-45
Chicken liver	60
Dry aged meats (eg, mortadella, salami, prosciutto)	2-45
Fava beans	Unknown
Kim chee	Unknown
Red wine	Variable
Sauerkraut	1-3
Smoked or pickled fish (eg, lox, caviar, pickled herring)	0-80
Soy sauce, fermented soy, miso	Varies
Tap beer	20-40
Yeast extract	2-60
Foods to Eat in Moderation	
American cheese, Parmesan cheese	<2
Canned, filtered beer	<2 per 12 oz (355 mL)
Havarti, brie	Thought to be low
Pepperoni	<2
Pizza (large commercial chains generally safe; avoid gourmet with aged cheeses and meats)	2 slices
White wine	<1 per 4 oz (120 mL)
Foods Without Restrictions	
Fresh dairy products (cottage cheese, cream cheese, fresh milk, ice cream, ricotta, sour cream, yogurt)	
Fresh meats (including fresh sausage)	
Processed meats (eg, lunch meat, hot dogs, ham)	
Spirits (eg, bourbon, gin, rum, vodka)	
Yeast bread products	

Medications to Avoid Completely

Antidepressants[a]
Amphetamines
Appetite suppressants
Asthma inhalants
Buspirone
Carbamazepine
Decongestants
Dextromethorphan
Dopamine
Ephedrine
Epinephrine
Guanethidine
Levodopa
Local anesthetics[b]
Meperidine
Methyldopa
Methylphenidate
Reserpine
Sympathomimetics

Tramadol
Tryptophan

[a] Tricyclic antidepressants may be used with caution by experienced clinicians in treatment-refractory populations.

[b] Those containing sympathomimetic vasoconstrictors.

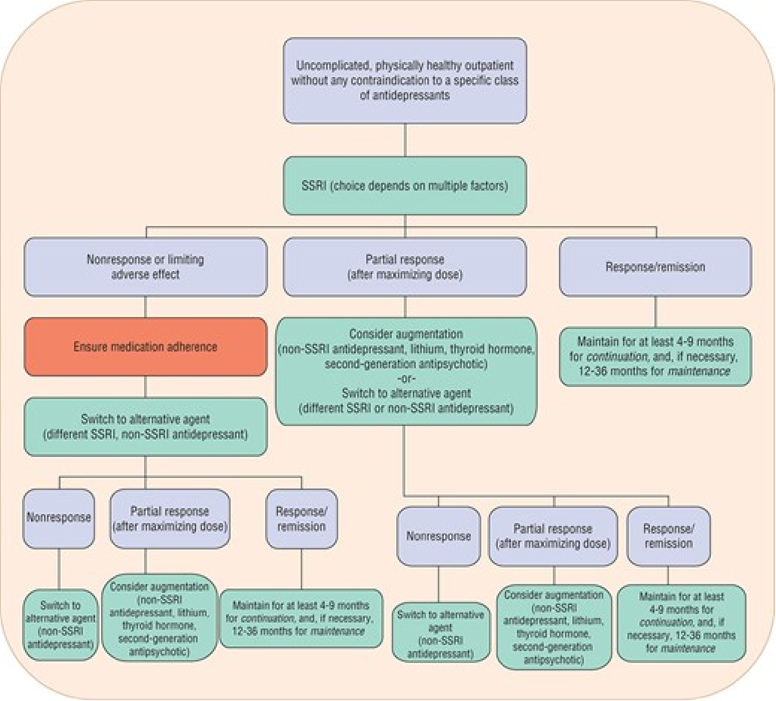
Data from References 61 and 81.

Second-Generation Antipsychotics

The second-generation antipsychotics (SGAs) aripiprazole, brexpiprazole, and quetiapine have been FDA approved for augmentation of antidepressant treatment. The combination of olanzapine/fluoxetine is FDA approved for treatment refractory depression. Additionally, cariprazine, olanzapine, and risperidone have been studied and are recommended in some treatment guidelines for refractory symptoms.[3,4] The specific mechanisms for these medications in MDD is not fully understood, but is thought to involve modulation of 5-HT and DA activity as they have variable activity at 5-HT_{1A}, 5-HT_{2A}, D_2, and D_3 receptors.[60] While these medications may be useful in the treatment of depression they are associated with the risk of metabolic complications and movement disorders. As discussed in detail in Chapter 87, "Schizophrenia," patients taking SGAs must have baseline and follow-up monitoring of metabolic parameters (weight, glucose, lipids, blood pressure) due to the risk of metabolic syndrome. Additionally, patients should be assessed for treatment emergent extrapyramidal symptoms (eg, parkinsonism, akathisia, dystonia). See Chapter 87 for greater detail.

FIGURE 88-3

Suggested algorithm for treatment of uncomplicated MDD. (SSRI, selective serotonin reuptake inhibitor.) Note: Both the British Association of Pharmacology (BAP) guidelines and the STAR*D trial suggest that switching and augmentation strategies are supported by stronger evidence compared to dose increases (among poor antidepressant responders).



Uncomplicated, physically healthy outpatient without any contraindication to a specific class of antidepressants
SSRI (choice depends on multiple factors)
Nonresponse or limiting adverse effect
Partial response (after maximizing dose)
Response/remission
Ensure medication adherence
Consider augmentation (non-SSRI antidepressant, lithium, thyroid hormone, second-generation antipsychotic) -or- Switch to alternative agent (different SSRI or non-SSRI antidepressant)
Maintain for at least 4-9 months for continuation, and, if necessary, 12-36 months for maintenance
Switch to alternative agent (different SSRI, non-SSRI antidepressant)
Nonresponse
Partial response (after maximizing dose)
Response/ remission
Nonresponse
Partial response (after maximizing dose)
Response/ remission
Switch to alternative agent (non-SSRI antidepressant)
Consider augmentation (non-SSRI antidepressant, lithium, thyroid hormone, second-generation antipsychotic)
Maintain for at least 4-9 months for continuation, and, if necessary, 12-36 months for maintenance
Switch to alternative agent (non-SSRI antidepressant)
Consider augmentation (non-SSRI antidepressant, lithium, thyroid hormone, second-generation antipsychotic)
Maintain for at least 4-9 months for continuation, and, if necessary, 12-36 months for maintenance

New/Investigational Agents with Novel Mechanisms

Medications with novel mechanisms have transitioned from proof of concept research to formal clinical trials and, in some cases, FDA approval (see Table 88-10). As mentioned above, while these agents do not directly alter activity of monoamines, they likely alter activity of monoamines as a secondary effect.

Ketamine, an older anesthetic agent, has increasingly been studied and used in the past decade for treatment resistant depression (TRD). Ketamine modulates glutamate activity via extrasynaptic *N*-methyl-*D*-aspartate (NMDA) receptor antagonism that is thought to increase synaptic glutamate activity resulting in increased BDNF activity and synaptogenesis.[30] Though not FDA approved for MDD, ketamine has demonstrated rapid antidepressant effects in sub-anesthetic intravenous doses (typically 0.5 mg/kg) for TRD in multiple studies.[19] Esketamine, the single *s*-isomer of ketamine, has a higher affinity for the NMDA receptor than the *r*-isomer.[82] An intranasal formulation of esketamine was FDA approved for TRD in 2019. The intranasal formulation overcomes some of the barriers associated with intravenous ketamine use, but has logistical barriers of its own. It requires supervised, in-clinic self-administration with two to six intranasal sprays per session and 2 hours of in-clinic observation after administration. In trials, patients received doses twice weekly for 4 weeks and variable dosing thereafter.[83] Overall both ketamine and esketamine appear to be relatively well tolerated at the doses used in clinical trials; however, transient psychotomimetic/dissociative effects and blood pressure elevation (10-20 mm Hg) occurred at higher rates than placebo with both agents.[19,83]

Based on research involving endogenous allopregnanolone levels and depression, specifically alterations in pregnancy and postpartum, brexanolone (exogenous allopregnanolone) was developed and FDA approved for the indication of postpartum depression in 2019. Administration involves a 60-hour stepped dose, intravenous infusion. First-pass metabolism precludes oral administration. Brexanolone is thought to exert antidepressant effect by allosteric modulation of $GABA_A$ receptors, which may increase 5HT and NE transmission.[24,84] The most common adverse medication reactions in brexanolone trials were headache, dizziness, and somnolence. In up to 4% of patients, the infusion was stopped due to excessive sedation or loss of consciousness.[84] It has a mandatory Risk Evaluation and Mitigation Strategies (REMS) program with Elements to Ensure Safe Use (ETASU). Analogues of brexanolone with oral bioavailability, including zuranolone, are in development but not yet FDA approved (Table 88-6).

TABLE 88-6

Novel Antidepressants

Medication	Administration	Comments
Ketamine[a] 10 mg/mL, 50 mg/mL, and 100 mg/mLDiluted for infusion	*Not FDA approved for MDD* *Based on clinical trials* Most common dose: 0.5 mg/kg IV infusion Dose range: 0.1-1 mg/kg IV infusion Frequency: Ranges from single dose up to 3 doses per week x 2-6 weeks	Sub-anesthetic dose Optimal duration of treatment not established Requires IV access Lower rate of dissociation compared with anesthetic doses of ketamine Limited sites of care May not be covered by insurance
Esketamine(Spravato) 28 mg per nasal spray device (14 mg per spray)	*FDA approved indications: Treatment resistant depression* One spray per nostril (28 mg) Repeat in 5 minutes for 56 mg and again in 5 minutes for 84 mg2x/week for 4 weeks then weekly for 4 weeks then every 1-2 weeks *MDD with suicidality* 84 mg 2x/week for 4 weeks	Sub-anesthetic dose Optimal duration of treatment not established Requires in office administration and observation post-dose Rate of dissociative symptoms comparable to low dose IV ketamine Limited sites of care Costly SPRAVATO REMS program: sedation, dissociation, use and misuse
Brexanolone(Zulresso) 100 mg/20mL	*FDA approved for postpartum depression only* Single 60-hr stepped infusion 0 to 4 hr 30 mcg/kg/hr 4 to 24 hr 60 mcg/kg/hr 24 to 52 hr 90 mcg/kg/hr 52 to 56 hr 60 mcg/kg/hr 56 to 60 hr 30 mcg/kg/hr	Requires hospitalization ZULRESSO REMS program: excessive sedation and sudden loss of consciousness Effect past 30 days not established Limited sites of care Costly: ~$30,000 per infusion

[a]not FDA approved for treatment of MDD.

IV, intravenous; REMS, Risk Evaluation and Mitigation Strategy.

Additional Adverse Events

Serotonin Syndrome

Any antidepressant that increases serotonergic neurotransmission can be associated with serotonin syndrome (SS), especially in situations where interactions increase release or duration of serotonin activity. The typical triad of symptoms seen in SS includes mental status changes, autonomic instability, and neuromuscular abnormalities (eg, hyperreflexia, myoclonus) which can be lethal.[86] As SS is primarily a diagnosis of exclusion, other causes of symptoms including neuroleptic malignant syndrome, anticholinergic toxicity, and malignant hyperthermia must be ruled out, with particular attention being paid to concurrent medications to guide differential diagnosis. Prompt medical attention is needed for any patient suspected of having SS syndrome, to discontinue all potentially causative agents, manage blood pressure and heart rate and maintain hydration.

Pharmacokinetics and Pharmacodynamics of Antidepressants

The PK of the antidepressants is summarized in Table 88-7.[60,73,87] The diversity of SSRIs is evident not only in their chemical structures but also in their PK profiles as the unique PK attributes of each SSRI can be used to guide treatment. For example, the long half-life of fluoxetine and its active metabolite norfluoxetine may be beneficial in instances of partial nonadherence. Conversely, caution must be taken to monitor for medication interactions prior to combining another medication with fluoxetine, fluvoxamine, or paroxetine.

TABLE 88-7

Pharmacokinetic Properties of Antidepressants

Generic Name	Elimination Half-Life[a]	Plasma Protein Binding (%)	Clinically Important Metabolites
Selective Serotonin Reuptake Inhibitors (SSRIs)			
Citalopram	33 hr	80	None
Escitalopram	27-32 hr	56	None
Fluoxetine	4-6 days[b]	94	Norfluoxetine[c]
Fluvoxamine	15-26 hr	77	None
Paroxetine	24-31 hr	95	None
Sertraline	27 hr	99[d]	None
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)			
Desvenlafaxine	11 hr	30	None
Duloxetine	12 hr	90	None
Levomilnacipran	12 hr	22	None
Venlafaxine	5 hr	27-30	*O*-Desmethyl-venlafaxine
TCAs			
Amitriptyline	9-46 hr	90-97	Nortriptyline
Desipramine	11-46 hr	73-92	2-Hydroxy-desipramine
Doxepin	8-36 hr	68-82	Desmethyl-doxepin
Imipramine	6-34 hr	63-96	Desipramine
Nortriptyline	16-88 hr	87-95	10-Hydroxy-nortriptyline
Mixed Serotonergic (Mixed 5-HT)			

Nefazodone	2-4 hr	99	*meta*-Chlorophenyl-piperazine
Trazodone	6-11 hr	92	*meta*-Chlorophenyl-piperazine
Vilazodone	25 hr	>95	
Vortioxetine	66 hr	98	
Norepinephrine/Dopamine Reuptake Inhibitor (NDRI)			
Bupropion	10-21 hr	82-88	Hydroxy-bupropion
			Threohydro-bupropion
			Erythrohydro-bupropion
Serotonin and α_2-Adrenergic Antagonists			
Mirtazapine	20-40 hr	85	None

[a] *Biologic half-life in slowest phase of elimination.*

[b] Four to 6 days with chronic dosing; norfluoxetine, 4 to 16 days.

[c] Take with food to increase area under the curve concentrations by greater than 60%.

[d] Increases 30% to 40% when taken with food.

Data from References 60,73, and 87.

Bioavailability is low (30%-70%) for most TCAs as a result of first-pass metabolism, which shows great interindividual variation.[89] The TCAs have a large volume of distribution and concentrate in brain and cardiac tissue in laboratory animals. They are bound extensively and strongly to plasma albumin, erythrocytes, α_1-acid glycoprotein, and lipoprotein.[89] The major metabolic pathways are demethylation, aromatic and aliphatic hydroxylation, and glucuronide conjugation, although enterohepatic cycling has been described.[89] Normally, the PK of TCAs is linear within the usual dosage range; however, the elimination half-lives can vary greatly among individual patients, which may be related to pharmacogenomic variability, primarily within CYP2D6 and CYP2C19.[89]

Venlafaxine is metabolized to an active metabolite, *O*-desmethylvenlafaxine, which contributes to the overall pharmacologic effect, and is also FDA approved as an antidepressant (desvenlafaxine). Immediate release (IR) venlafaxine is generally dosed twice daily to avoid end of dose discontinuation symptoms, while extended release venlafaxine and desvenlafaxine have a longer duration of action and can be dosed once daily.[60] Bupropion is metabolized to multiple active metabolites (Table 88-7), and there are three formulations of bupropion hydrochloride (immediate release, sustained release, and extended release), which are equivalent on a total daily dose basis as well as a bupropion hydrobromide formulation that can be converted to equivalent hydrochloride doses.[90] The bupropion peak plasma concentrations are lower for the sustained-release formulation, which are believed to contribute to a lower seizure risk.[90] Mirtazapine undergoes biotransformation to several metabolites[91,92]; however, it is primarily eliminated unchanged in the urine. The mirtazapine metabolites are present at such low plasma concentrations they minimally contribute to the overall pharmacologic profile. Levomilnacipran is primarily metabolized via CYP3A4 with renal elimination of over 50% of the dose.[60]

Brexanolone undergoes extensive first-pass metabolism and is only available in intravenous formulation.[80] Ketamine (IV) and esketamine (nasal) undergo extensive oxidative metabolism and have elimination half-lives of approximately 2 hours and 7 to 12 hours, respectively.

An important PK difference between oral selegiline (FDA approved only for Parkinson disease) and transdermal selegiline impacts their pharmacodynamic profile. Oral selegiline undergoes extensive first-pass metabolism resulting in bioavailability of 4% versus 73% for the transdermal formulation.[80] At the low CNS concentrations achieved with the oral formulation, selegiline selectively inhibits MAO-B resulting in increased DA levels (hence, the use for Parkinson disease). Nonselective inhibition of both MAO-A (resulting in increased NE and 5HT levels) and MAO-B, which is thought to be important to achieve an antidepressant effect, which occurs at the higher CNS concentrations only achieved with the transdermal formulation.[80]

Antidepressant Altered Pharmacokinetics

Antidepressants may have significantly altered PK in patients with hepatic or renal disease; however, the data regarding the altered PK parameters are often derived from small, single-dose studies. Changes are variably reported as decreased clearance, increased area under the curve (AUC) or increased half-life.[91,92] In patients with chronic liver disease, clearance may be decreased 30% (citalopram, mirtazapine) to over 70% (duloxetine, sertraline) and half-life may be increased twofold (citalopram, paroxetine) to threefold (duloxetine, fluoxetine). The AUC of TCAs and bupropion have been reported to increase threefold in cirrhosis.[92] Duloxetine is not recommended in patients with significant hepatic impairment.

Renal impairment and end-stage renal disease (ESRD) do not significantly alter antidepressant PK, with notable exceptions. The half-life of citalopram, escitalopram, and paroxetine may increase 30% to 40%.[91] The AUC of bupropion desvenlafaxine, duloxetine, mirtazapine, and venlafaxine may increase twofold.[91] Duloxetine labeling recommends against use in patients with estimated glomerular filtration rate (eGFR) <30 mL/min/1.73 m^2.[91] Bupropion metabolites have also demonstrated accumulation in ESRD. Renal failure does not alter nortriptyline metabolism, but the 10-hydroxy metabolite may accumulate, and protein binding may be diminished, with resulting enhanced sensitivity to the medication.[89]

In patients with significant renal or hepatic impairment, it is reasonable to initiate treatment with 50% lower dose and titrate to 50% to 75% of maximum dose based on tolerability and response. Patients should be monitored for electrolyte abnormalities and low platelets that can increase risk of arrhythmias and bleeding. Additionally, lower doses and cautious monitoring are prudent when patients are on concomitant medications with overlapping toxicity profiles.

Plasma Concentration and Clinical Response

For the newer antidepressants, a strong correlation between plasma concentration and clinical response or tolerability has not been established, while this has been established for some TCAs (eg, amitriptyline, nortriptyline, desipramine, and imipramine). However, the best established therapeutic range is for nortriptyline (50-150 ng/mL [mcg/L; 190-570 nmol/L]),[89] which appears to demonstrate a curvilinear plasma concentration-response relationship.

Clinical response, not plasma concentration, should dictate dosage adjustments, as some patients with plasma concentrations outside the suggested therapeutic range respond to treatment, whereas others are nonresponsive even with “therapeutic” plasma concentration.

Plasma Concentration Monitoring

Because of interindividual variations in plasma concentrations achieved by a given dose, interpretation of plasma concentrations can be very difficult for the TCAs.[89] Although plasma concentration monitoring is not performed routinely, some indications include inadequate response, relapse, serious or persistent adverse medication reactions, use of higher-than-standard doses, suspected toxicity, older adult patients, pregnant patients, cardiac disease, suspected nonadherence, and suspected PK interactions. If plasma concentration monitoring is used to detect nonadherence, a cutoff as low as 30 ng/mL (mcg/L; ~110 nmol/L) for the TCAs has been suggested to avoid confusion with low bioavailability or unusually rapid metabolism. Blood samples for plasma concentration determinations should be obtained at steady state, usually after a minimum of 1 week at constant dosage. Sampling should be performed during the elimination phase, usually in the morning, 12 hours after the last dose. Samples collected in this manner are comparable for patients on once-, twice-, or thrice-daily regimens.[89]

Medication Interactions

Interactions fall into two broad categories: PK and PD medication interactions, with the PK interactions being the most common. Antidepressants are primarily substrates for cytochrome P450 enzymes and variably act as inhibitors of the enzymes (see Table 88-8).[60,88]

TABLE 88-8

Antidepressants and Cytochrome (CYP) P450 Enzyme Inhibitory Potential

	CYP Enzyme Inhibition			
Medication	**1A2**	**2C**	**2D6**	**3A4**
Bupropion	0	0	+++	0

Data from References 60 and 88.

Pharmacokinetic Interactions

Interactions may occur when an antidepressant is coadministered with another medication metabolized through the cytochrome P450 system. Two of the cytochrome P450 system isoenzymes, CYP2D6 and CYP3A4, are responsible for the metabolism of most currently marketed medications.[88] The ability of an antidepressant to inhibit the activity of these enzymes will be a significant contributory factor in determining its capability to cause a PK interaction when administered concomitantly. Table 88-8 shows the cytochrome P450 enzyme inhibitory potential of antidepressant agents. Patients taking substrates of these enzymes should be monitored closely if started on an antidepressant with inhibitory potential. Select examples can be found in Table 88-9.

TABLE 88-9

Select Pharmacokinetic Interactions of Antidepressants

Antidepressant	Interacting Medication/Medication Class	Effect
Selective Serotonin Reuptake Inhibitors		
Citalopram and escitalopram	Omeprazole	Increased concentrations of citalopram and escitalopram
Fluoxetine	Alprazolam	Increased concentrations and half-life of alprazolam; increased psychomotor impairment
	Antipsychotics (eg, aripiprazole, haloperidol)	Increased antipsychotic concentrations; increased extrapyramidal symptoms
	β-Adrenergic blockers	Increased metoprolol concentrations; increased bradycardia; possible heart block
	Carbamazepine	Increased concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Phenytoin	Increased concentrations of phenytoin; symptoms of phenytoin toxicity
	Tamoxifen	Decreased conversion of tamoxifen to active metabolites
	TCAs	Markedly increased TCA concentrations; symptoms of TCA toxicity
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Fluvoxamine	Alosetron	Increased alosetron AUC (sixfold) and half-life (threefold)
	Alprazolam	Increased AUC of alprazolam by 96%, increased alprazolam half-life by 71%; increased psychomotor impairment
	β-Adrenergic blockers	Fivefold increase in propranolol concentration; bradycardia and hypotension
	Carbamazepine	Increased concentrations of carbamazepine; symptoms of carbamazepine toxicity
	Clozapine	Increased clozapine concentrations; increased risk for seizures and orthostatic hypotension
	Diltiazem	Bradycardia
	Methadone	Increased methadone plasma concentrations; symptoms of methadone toxicity
	Ramelteon	Increased AUC (190-fold) and C_{max} (70-fold)
	TCAs	Increased TCA concentration; symptoms of TCA toxicity
	Theophylline and caffeine	Increased concentrations of theophylline or caffeine; symptoms of theophylline or caffeine toxicity
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval

	Warfarin	Increased effect of warfarin
Paroxetine	Antipsychotics (eg, aripiprazole, haloperidol)	Increased antipsychotic concentrations; increased CNS and extrapyramidal symptoms
	β-Adrenergic blockers	Increased metoprolol concentrations; increased bradycardia; possible heart block
	Tamoxifen	Decreased conversion of tamoxifen to active metabolites
	TCAs	Markedly increased TCA concentrations; symptoms of TCA toxicity
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Sertraline	Methadone	Increased methadone levels
Serotonin–Norepinephrine Reuptake Inhibitors		
Venlafaxine and desvenlafaxine	CYP3A4 inhibitors	May increase levels of venlafaxine and *O*-desmethylvenlafaxine especially in CYP2D6 poor metabolizers
Duloxetine	Metoprolol	May increase metoprolol levels twofold
	Tamoxifen	Decreased conversion of tamoxifen to active metabolites
	Thioridazine	Thioridazine C_{max} increased; prolonged QTc interval
Levomilnacipran	CYP3A4 inhibitors	Clinically relevant increases in levomilnacipran concentrations may occur
Mixed Serotonergic (Mixed 5-HT)		
Vilazodone	CYP3A4 inhibitors	Maximum vilazodone dose 20 mg with coadministration of potent CYP3A4 inhibitor
Vortioxetine	CYP2D6 inhibitors	May need to reduce vortioxetine dose by half with coadministration of potent CYP2D6 inhibitor
Serotonin and α-2-Adrenergic Antagonist		
Mirtazapine	Carbamazepine	Mirtazapine concentration decreased (60%)
Norepinephrine and Dopamine Reuptake Inhibitor		
Bupropion	Tamoxifen	Decreased conversion of tamoxifen to active metabolites

AUC, area under the time concentration curve; C_{max}, maximum concentration; MAOI, monoamine oxidase inhibitor.

Note: Any medication that augments serotonergic function may impact bleeding risk and should be used with caution in patients receiving NSAIDs or other medications with hematologic effects.

Data from References 2,60,73, and 88.

Because the TCAs are metabolized in the liver through the cytochrome P450 system, they may interact with other medications that modify hepatic enzyme activity or hepatic blood flow. TCAs are also extensively protein bound, which can result in interactions through displacement from protein-binding sites. Many commonly used medications can interact when given concurrently with TCAs.

As nefazodone use has been severely limited due to its potential to induce liver toxicity, and trazodone is primarily used as a non-FDA-approved hypnotic at low doses, neither of these agents are likely to be involved in clinically significant medication interactions. However, nefazodone is a potent inhibitor of CYP3A4.[88] Vilazodone is primarily metabolized via CYP3A4 and vortioxetine is primarily metabolized via CYP2D6 and both require dose adjustment with inhibitors.[60,62]

Pharmacodynamic Medication Interactions

Certain PD medication interactions that may occur with antidepressants are concerning and require close monitoring. For example, concurrent use of serotonergic antidepressants with other medications that augment serotonergic function can increase the risk of SS with some combinations conferring a higher risk than others.[86]

Tramadol presents as an example of a PK interaction increasing the risk of a PD interaction. When tramadol is coadministered with strong CYP2D6 inhibitors, the decrease in metabolism may result in higher levels of tramadol, which also exhibits SNRI effects. Therefore, high doses of the combination have been reported to cause serotonin syndrome.[86,93]

See Table 88-10 for key examples of PD interactions.[60,86,93–96]

TABLE 88-10

Select Pharmacodynamic Medication Interactions of Antidepressants

Medication/Medication Class	Antidepressants/Antidepressant Class	Effect and Management
NSAIDs Aspirin Anticoagulants Antiplatelet agents	SSRIs, SNRIs, TCAs, trazodone, vilazodone, vortioxetine	• FDA warning for increased risk of bleeding • Number needed to harm with NSAIDs = 82 vs >700 with SSRI alone • Assess for baseline bleeding risk and monitor closely • Educate at risk patients regarding signs of bleeding • Consider histamine-2 (H_2) antagonist in high-risk patients
Triptans	MAOIs, SSRIs, and SNRIs	• FDA warning in labeling • Very low risk • Monitor for signs of serotonin syndrome when frequent high doses are used • Triptan toxicity possible when almotriptan, rizatriptan, sumatriptan, or zolmitriptan are combined with MAO inhibitors
Linezolid	All serotonergic antidepressants	• Linezolid is weak, reversible, nonselective, MAOI • FDA labeling recommends against use with other MAOIs and recommends discontinuing antidepressants if linezolid is started • Actual rate of serotonin syndrome with combination reported at <1% • Abrupt discontinuation of antidepressants can have negative consequences • If linezolid is indicated and patient is already on an antidepressant, monitor for signs of serotonin syndrome upon initiating combination • If patient is on short course of linezolid and in need of treatment for depression, consider postponing antidepressant initiation until course is complete
Tramadol	Bupropion, duloxetine, fluoxetine, paroxetine	• Decreased metabolism results in increased SNRI activity of tramadol • Rare cases of high dose tramadol combined with CYP2D6 inhibitors resulting in serotonin syndrome have been reported • Monitor for increased signs of serotonin syndrome and decreased analgesic response when combination is used

Data from References [60, 86,93–96].

There are two types of PD medication interactions that may occur between antidepressant medications and NSAIDs. An increased risk for abnormal bleeding (eg, upper GI and intracranial hemorrhage) associated with combined antidepressants and NSAID use is a potentially very serious pharmacodynamic interaction.[95] This interaction is likely mediated by serotonergic mechanisms that occur at the platelet level. Additionally, NSAIDs may lessen the efficacy of SSRIs; however, the evidence is insufficient to draw firm conclusions.[95] However, given the volume of prescriptions for both NSAIDs and SSRIs, this is an area of pharmacotherapy that certainly deserves further research and thoughtful prescribing practices.

Lastly, refer to the section "Monoamine Oxidase Inhibitors" above and Table 88-5 regarding the hypertensive crisis that may result following coadministration of MAOIs and other medications that increase vasopressor response (eg, amphetamines). Notably, MAOIs and TCAs have been coadministered safely in TRD patients with apparent increased efficacy compared with monotherapy; however, severe reactions (eg, hypertensive crisis) and fatalities have occurred.[2,89] Therefore, this combination should be used sparingly by experienced clinicians and monitored extremely carefully.

Alternative Pharmacotherapy

The APA Task Force on Complementary and Alternative Medicine (CAM) as well as CANMAT guidelines include evidence-based and consensus-based recommendations on the use of CAM for the treatment of MDD.[59,97] While these recommendations are not the focus of this chapter, clinicians treating patients with MDD should be cognizant of them.

Omega-3 Fatty Acids

Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) omega-3 fatty acids are generally low-risk and demonstrate variable benefit as augmentation in the treatment of MDD. Use of EPA alone or the combination of EPA/DHA is likely more effective than DHA alone. As these agents may increase bleeding risk, their use should be carefully considered in patients taking SSRIs and other concomitant medications associated with bleeding risk (eg, NSAIDs, anticoagulants).

St. John’s Wort

There is a lack of consensus regarding St. John’s wort for the treatment of MDD. Furthermore, St. John’s wort induces hepatic metabolic enzymes and is associated with significant interactions. The APA Task Force conservatively states that St. John’s wort may be reasonable for some individuals with mild-to-moderate MDD while CANMAT considers it to have level 1 evidence as first-line therapy for mild-to-moderate MDD.[2,4] Further, the BAP guidelines state a “standardized” preparation of St. John’s wort “could be considered” in patients with mild-to-moderate MDD, if other first-line medications are not an option.[3]

S-Adenosyl-L-Methionine (SAMe)

The use of SAMe received a favorable review by the APA Task Force. However, the final consensus was that more rigorous studies need to confirm the efficacy of SAMe for treating MDD. The CANMAT guidelines consider SAMe as a second-line augmentation strategy while the BAP guidelines state that evidence is developing for use of SAMe as an augmentation strategy in the treatment of MDD.[3]

Folate

The three compounds in this category are (a) folic acid, (b) folinic acid, and (c) 5-methyltetrahydrofolate (5-MTHF) as these compounds are involved in the synthesis of key neurotransmitters such as 5-HT. The APA task force states that augmentation with these compounds is reasonable, but more work is needed to clarify which subgroup of patients may achieve the greatest response.[59] For example, in one study, only females responded to folic acid augmentation of fluoxetine treatment. Regardless, CANMAT guidelines consider folate supplementation a third-line augmentation strategy.[4]

Special Populations

Older Adult Patients

Depression in older adults is a major public health problem as many older adult patients with depression are inadequately treated, or have their depression missed or mistaken for another disorder, such as dementia. In these patients, depressed mood, the typical signature symptom of depression, may be less prominent than other depressive symptoms such as loss of appetite, cognitive impairment, sleeplessness, anergia, and anhedonia. Previous research supports that somatic (physical) complaints (eg, pain, fatigue, gastrointestinal symptoms) present more frequently in older adults with depression. However, there are many confounders that may account for this (eg, higher rates of physical illness).[34] Appropriate recognition and treatment of depression in older adults is extremely important as individuals 65 years of age and older have a high rate of suicidality. Increased suicide attempts in older adults with depression have been associated with access to firearms, diminished cognitive functioning, sleep disruptions, poor social interactions, and inattention among primary caregivers.[98]

Before initiating antidepressant treatment, a complete physical examination should be performed. When prescribed antidepressants, older adults may be either overtreated or under-treated. Overtreatment occurs when age-related PK and PD factors are overlooked and under-treatment results from an overly conservative approach as a result of the patient's advanced age or concurrent medical problems. In older adults, SSRIs are usually selected as first-line treatment, and this may enable the clinician to avoid some of the problematic intolerances commonly associated with TCAs (eg, sedative, anticholinergic, and cardiovascular adverse reactions). Furthermore, there is evidence to suggest that the long-term use of antidepressants such as SSRIs in older adults, administered with either psychotherapy or clinical management, may prevent a depressive relapse.[34,35] Hyponatremia is more common in elderly females, especially in those taking concomitant diuretics. Mirtazapine has been shown to be an effective antidepressant in adults older than 65 years of age and better tolerated than the SSRI paroxetine. Furthermore, secondary measures of anxiety and sleep were improved following mirtazapine administration.[99] In addition to sleep benefits, mirtazapine can be helpful in improving appetite which is commonly diminished in older adults with depression. For those patients whose depressive symptoms include lack of overall energy, use of bupropion may capitalize on the stimulant effect of this medication. Regardless of the specific antidepressant chosen, the effect sizes for antidepressants as a pharmacological class, compared to placebo, may be smaller in older adult patients than in younger adult populations.[3]

Pediatric Patients

Accumulating evidence indicates that childhood depression occurs quite commonly and symptoms of depression in the young may vary from accepted diagnostic criteria to include several nonspecific symptoms such as boredom, anxiety, somatic complaints (eg, stomach ache), and impulsivity.[100]

Data collected under controlled conditions that support the efficacy of antidepressants in children and adolescents are sparse, and only fluoxetine and escitalopram are FDA-approved for depression in patients younger than 18 years of age, although other antidepressants (eg, sertraline) have been studied in this population.[100] The Treatment of Adolescent Depression Study (TADS) found that the combination of fluoxetine and CBT was superior to fluoxetine monotherapy or CBT alone in adolescents 12 to 17 years of age.[101] The Treatment of Resistant Depression in Adolescents (TORDIA) study switched adolescents 12 to 18 years of age with SSRI-resistant depression to venlafaxine or sertraline with or without CBT after nonresponse to antidepressant. Overall this study found no difference in outcomes between the two medications and also found no difference in outcomes when CBT was added to medication.[102] Additionally, the Adolescent Depression Antidepressant and Psychotherapy Trial (ADAPT) did not find a benefit of adding CBT to SSRI therapy in adolescents 11 to 17 years of age.[103]

The use of antidepressants in children and adolescents was complicated when, the FDA issued a boxed warning in the product labeling for antidepressant medications warning clinicians and patients of the increased risk for suicidal ideation and behavior when antidepressants are used in this population. Results of subsequent studies attempting to elucidate the risk of antidepressants in young patients have varied. A meta-analysis of published and unpublished clinical trials supported an increased risk; however, the study was impeded by limited data access. In contrast, several retrospective longitudinal reviews of antidepressant use in children refute the increased risk of suicide attempts or deaths.[104] Furthermore, studies demonstrated a decreased rate of prescribing antidepressants and an increase in deaths by suicide after the warning appeared in labeling.[105]

The treatment of depression in children remains challenging, as depression can be difficult to diagnose and, once identified, treat. Furthermore, differences in efficacy between medication and placebo may be small and not significant in children below the age of 13 years.[3] However, antidepressants (in particular, the SSRIs) remain viable treatment options when prescribed and monitored appropriately.

Pregnant and Lactating Patients

The crucial decision as to whether to use antidepressants during pregnancy continues to be debated and must always include a risk-benefit analysis based upon the available evidence at the time of treatment. Approximately 14% of pregnant individuals develop clinically significant depression during pregnancy.[106] Furthermore, it has been documented that those who discontinued antidepressant therapy before or during pregnancy were five times more likely to have a relapse than those who continued treatment.[107] While numerous studies, reviews, and meta-analyses have been published over the last decade, the absolute risk of antidepressants in pregnancy is still not clear due to methodological issues and confounding factors (eg, prenatal care, continued depressive symptoms during treatment, medical and psychiatric comorbidities, and substance use).[108] An approximate 25% relative increase in congenital heart defects associated with SSRIs is the most consistent finding; however, the increase in risk ranges from 10% to a twofold increase across studies.[108] Other findings have included increased risk of low birth weight and newborn respiratory distress.[106] An oft-cited study reported a sixfold greater likelihood of persistent pulmonary hypertension of newborn infants exposed to an SSRI after the 20th week of gestation; however, the degree of this risk has been debated.[109] These are selected examples of studies assessing both risks and benefits of antidepressants in pregnancy. A full exploration of the conflicting literature on this topic is beyond the scope of this chapter.

Four therapeutic principles have been proposed to guide the clinician in treating pregnant individuals or individuals who desire pregnancy: (a) Pregnancy does not protect against the occurrence of depression, and the likelihood of relapse is very high in untreated individuals with recurrent illness. (b) Depression during pregnancy adversely affects child development, and prenatal depression may adversely affect the offspring. (c) When attempting to balance benefit and risk, transient postnatal behavioral abnormalities in the offspring of pregnant individuals receiving pharmacotherapy must not be assumed to portend long-term compromise. (d) SSRIs, the most commonly used and best-tolerated treatment for depression, carry a small but significant risk for a serious medical consequence.[110]

The APA and the American College of Obstetricians and Gynecologists have a report discussing the treatment of depression during pregnancy. One of the prominent conclusions of this report was that *both* antidepressant treatment and untreated depression have been associated with potential problems during pregnancy. However, studies to date have not been able to adequately control for all the necessary variables involved in birth outcomes (eg, maternal depressive disorder) and more work needs to be done.[111]

In summary, the risks and benefits of medication therapy during pregnancy must always be weighed, and concerns about the risks of untreated depression during pregnancy should be considered. These include the possibility of low birth weight secondary to poor pregnancy weight gain, suicidality, potential for hospitalization, potential for relationship discord, inability to engage in appropriate obstetric care, and difficulty caring for other children. Several different approaches exist for dealing with pregnancy and antidepressant use. First, discontinuation of an antidepressant before conception is an option for individuals who are stable and appear likely to remain well while not taking antidepressant medication (eg, no history of recurrence upon discontinuation, no history of severe symptoms or suicidality, stable psychosocial supports). Second, continuation of the antidepressant until conception may be reasonable and one with the lowest risk for the fetus should be chosen in individuals of child bearing potential or those trying to conceive. For those who have a history of depressive relapse after medication discontinuation, the antidepressant should be continued throughout pregnancy. There is a great deal of uncertainty regarding long-term antidepressant exposure in infants exposed through human milk due to the lack of data. However, sertraline is recommended and appears in relatively low concentrations in human milk and in samples taken from infants.[112] The risks of not treating depression in a patient who is pregnant or providing milk to an infant should not be underestimated or minimized. Additional information can be found in Chapter 99, Pregnancy and Lactation.

Relative Resistance and Treatment-Resistant Depression

The majority of patients with TRD likely have had inadequate (low dose, short duration) therapy (relative resistance). This theory is supported by data from the National Institute of Mental Health (NIMH) Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, which is generally considered to be one of the premier antidepressant trials among patients with depressive disorders.[56,113] According to this study one in three patients with depression who previously did not achieve remission with an antidepressant (citalopram) became symptom free with an additional medication (bupropion SR or buspirone) and one in four achieved remission after switching to a different antidepressant (bupropion SR, sertraline, or venlafaxine XR). Furthermore, patients can be switched to another medication within the same class.[114] For example, patients in the STAR*D study not responding to an initial SSRI were shown to be as likely to respond to another SSRI as they were to a medication from a different class.[115] Other key findings of STAR*D include the importance of maximizing dose (higher doses associated with higher remission rates) and adequate trial duration of at least 8 to 12 weeks before deeming a medication ineffective.[56] The BAP guidelines place a higher level of confidence in both augmentation and switching strategies, compared to dosage increase approaches.[3]

Although several different definitions for TRD have been proposed, the most widely accepted is depression that has not achieved remission after two optimal antidepressant trials, which represents more than 40% of patients with MDD treated with antidepressants.[115] Three pharmacologic approaches that have been used with success for TRD include the following:

1. The current antidepressant may be stopped and another agent initiated (ie, switching). For example, the STAR*D trial compared switching to mirtazapine (up to 60 mg/day) versus nortriptyline (up to 200 mg/day) after two consecutive ineffective medication treatments.[115] In the mirtazapine group, 12.3% of patients met the remission criterion of a score of 7 or less on the Hamilton Rating Scale for Depression (HAM-D), while

19.8% of nortriptyline patients met this criterion at the end of 14 weeks.

2. The current antidepressant can be augmented by the addition of another agent such as lithium, or another antidepressant (ie, combination antidepressant treatment). For example, the STAR*D trial evaluated the addition of lithium or triiodothyronine (T_3) to current antidepressant treatment. After approximately 10 weeks, T_3 augmentation resulted in higher remission rates (24.7%) compared with lithium (15.9%). However, the differences between these two augmentation strategies were modest and not statistically significant.[116] Although T3 and lithium demonstrated similar remission rates in this seminal trial, the BAP guidelines provide a stronger recommendation rating for lithium (ie, "A") compared to T3-based approaches (ie, "B").[116] In contrast, the CANMAT guidelines consider both agents second-line for augmentation with level 2 evidence.[4]
3. The use of SGAs to augment the antidepressant response is increasing. Aripiprazole, brexpiprazole, and quetiapine are FDA approved for adjunctive treatment for MDD. Aripiprazole and quetiapine have been recommended as first-line agents to augment an antidepressant medication.[4] In a predominantly male population in the Veterans Health Administration, augmentation with aripiprazole was found to be more effective than switching to bupropion but no different from bupropion augmentation.[117]

The APA practice guideline for the treatment of patients with MDD offers direction for managing patients whose symptoms are refractory to medications. These guidelines advise that if patients are still symptomatic after 6 to 8 weeks of medication, a reappraisal of the treatment regimen should be considered.[2] Those with partial response should consider changing the dose, augmenting the antidepressant, or adding psychotherapy or ECT. For those with no response, options include changing to a different antidepressant or adding psychotherapy or ECT. Again, the BAP guidelines suggest that stronger evidence exists for switching or augmentation strategies compared to dose increases in patients with inadequate antidepressant response.[3] Comorbid medical or psychiatric conditions should be identified and treated because they may complicate treatment.

⑥ Before changing a patient's treatment, the clinician is advised to evaluate the adequacy of the medication dosage and adherence with the prescribed regimen. Issues to be addressed in assessing the patient who has not responded to treatment include the following:

1. Is the diagnosis correct?
2. Does the patient have a psychotic depression?
3. Has the patient received an adequate dose and adequate duration of treatment?
4. Do adverse medication reactions preclude adequate dosing?
5. Is patient adherence to the prescribed regimen appropriate?
6. Was a stepwise approach to treatment used?
7. Was treatment outcome adequately measured?
8. Is there a coexisting or pre-existing medical or psychiatric disorder?
9. Are there other factors that interfere with treatment?

Personalized Pharmacotherapy

⑦ Pharmacogenetic (PGx) applications in psychiatry have been explored for some time. Multiple commercially available PGx tests are now available and in patients who present with the testing already completed or for whom a test is ordered, evidence-based guidelines produced by the Clinical Pharmacogenomics Implementation Consortium (CPIC) can help determine test interpretation (www.cpic.org). CPIC does not specifically recommend testing in patients, but rather serves as a resource for clinicians who are presented with PGx testing results and are looking for assistance in their interpretation. Therefore, while this testing may, one day, be routinely used to guide pharmacotherapy, it is not utilized routinely in practice for several reasons.[118] Included on several of the commercially available test are genes associated with PK parameters that have long been one of the primary considerations when choosing among the antidepressants, particularly within a medication class.[2] For example, PK parameters help the clinician choose a particular SSRI (eg, longer fluoxetine half-life for partial nonadherence). The data regarding the interpretation of PGx testing results for the

PK genes is more concrete than that associated with PD genes.

A clinician can use other aspects of a medication's pharmacological profile to tailor the treatment to a particular patient. For example, antidepressants can generally be classified as either activating or sedating based upon their mechanism of action, and this is often a major consideration in antidepressant choice. Medications that promote noradrenergic activity (eg, bupropion, venlafaxine) or serotonin (eg, SSRIs) may be activating upon initiation and therefore poor choices for a patient suffering from significant insomnia. In contrast, mirtazapine and trazodone have been shown to improve sleep, likely due to antagonism of H_1 and 5-HT_{2A} receptors.[67] Furthermore, doxepin is FDA approved (in lower doses compared to those used for depression) as pharmacotherapy for primary insomnia.[60]

EVALUATION OF THERAPEUTIC OUTCOMES

⑧ Several monitoring parameters, in addition to plasma or serum concentrations, are useful in managing patients (Tables 88-3 and 88-11).[2,60] Patients must be monitored for adverse medication reactions, such as sedation and anticholinergic effects, and for remission of previously documented target symptoms. The presence of adverse medication reactions does not necessarily indicate adequate or excessive dosage. In addition, changes in social and occupational functioning should be assessed. Patients receiving SNRIs should have their blood pressure monitored at regular intervals. Patients older than 40 years of age should receive a pretreatment ECG before starting TCA therapy, and follow-up ECGs should be performed periodically to assess for arrhythmias. Patients should be monitored for the emergence of suicidal ideation after initiation or discontinuation of any antidepressant, especially if other risk factors for death by suicide (eg, sleep disturbances) are present. If significant activation or insomnia occurs upon antidepressant initiation, a short-term anxiolytic or hypnotic may be appropriate.[67] Weight gain and sexual dysfunction, common adverse reactions associated with most antidepressants, may increase nonadherence and should be monitored and discussed with the patient (Table 88-11).

TABLE 88-11

Adverse Medication Reactions and Monitoring Parameters Associated with Select Antidepressants

Medication	Adverse Medication Reaction	Monitoring	Comments
Antidepressants from Each Pharmacologic Class			
Common to all antidepressants			
	Suicidality	Behavioral changes Mental status	(US boxed warning) for all antidepressants; caregivers should be alerted to monitor for acute changes in behavior (especially early in treatment)
Selective Serotonin Reuptake Inhibitors (SSRIs)			
Common to all			
	Anxiety or nervousness	Assess severity and impact on patient functioning and quality of life	Most prominent on initial treatment; lower initial doses recommended in patients with prominent anxiety
	Hyponatremia	Serum sodium	More likely in older adult females; sodium may decrease within 72 hours of initiating antidepressant
	Nausea	Frequency and severity	May improve with slower dose titration

	Sleep changes (insomnia and somnolence)	Sleep patterns	Among SSRI class: fluoxetine may be more activating; paroxetine may be more sedating
	Sexual dysfunction	Assess severity and impact on patient functioning and quality of life	Spontaneous self-reporting may be low; clinician should assess symptoms; reversible on medication discontinuation
SSRI-Specific			
Citalopram (possibly escitalopram)	QTc interval prolongation	Electrocardiogram; electrolytes (eg, potassium, magnesium)	Caution use in "at-risk" patients (eg, electrolyte disturbance); discontinue if QTc persistently >500 ms or increased >50 ms over baseline
Paroxetine	Anticholinergic effects	Symptoms: dry mouth, constipation, urinary retention, mental status	Avoid in older adults
Serotonin–Norepinephrine Reuptake Inhibitors (SNRIs)			
Common to all			
	Cardiovascular changes	Increases in blood pressure; heart rate	Possibly less likely with duloxetine; may need to lower/discontinue dose
	Insomnia	Sleep patterns	Possibly less likely with duloxetine
	Nausea	Frequency and severity	May improve with slower dose titration
	Sexual dysfunction	Assess severity and impact on patient functioning and quality of life	Spontaneous self-reporting may be low; clinicians should assess symptoms; reversible on medication discontinuation
	Sweating	Frequency and severity	May require change in therapy
SNRI-Specific			
Desvenlafaxine	Dose-related hyperlipidemia	Lipid profile	Elevations in total cholesterol, low-density lipoproteins, and triglycerides
Duloxetine	Liver toxicity	Liver function tests	May be transient upon initiation or sustained
Mixed Serotonergic Effects (Mixed 5-HT)			
Nefazodone	Liver toxicity	Liver function tests	Nefazodone boxed warning in the United States for hepatotoxicity
Trazodone	Orthostatic hypotension	Blood pressure, pulse	May be more severe as compared with other antidepressants; rate-limiting adverse medication reactions
	Priapism	Patient report of sexual	Patient should seek medical attention for prolonged erection (ie, >4 hr)

		dysfunction, especially painful erection	
Vilazodone and vortioxetine	Nausea	Frequency and severity	Most common dose limiting adverse reaction
Serotonin and α_2-Adrenergic Antagonist			
Mirtazapine	Weight gain	Body weight	Frequently occurring and significant (>7% over baseline) weight gain among adults; diet mediated
Norepinephrine and Dopamine Reuptake Inhibitor (NDRI)			
Bupropion	Seizure activity	Electroencephalogram if indicated	See Table 88-3 for proper dosing, which can help decrease seizure risk; caution use in patients with eating disorders or alcohol use disorders

Data from References 2,60,62,73,74, and 80.

In addition to the clinical interview, psychometric rating instruments (such as those highlighted earlier in this chapter and in Chapter e81) allow for rapid and reliable measurement of the nature and severity of depressive and associated symptoms. It is helpful to administer the rating scales prior to treatment, 2 to 4 weeks and 8 to 12 weeks after initiation of therapy, and periodically thereafter. It is important to note that lack of robust response at 2 to 4 weeks does not necessarily predict lack of response at 8 to 12 weeks.[56] Interviewing a family member or friend (with the patient's permission) regarding symptoms and daily functioning also can assist in assessment of progress, as they may notice symptom improvements before the patient. Patients should be monitored at more frequent intervals early in treatment, particularly for suicidality. Monitoring is then continued at regular intervals throughout the continuation and maintenance phases of treatment and assessing for reemergence of target symptoms continued for several months after antidepressant therapy is discontinued.

Finally, one useful set of criteria that can be used with a variety of psychometric scales uses the following definitions: (a) *nonresponse* is less than a 25% decrease in baseline symptoms, (b) *partial response* is a 26% to 49% decrease in baseline symptoms, and (c) *partial remission or response* is greater than a 50% decrease in baseline symptoms.[53] Consistent with other recommendations, *remission* is a return to baseline functioning with no symptoms present.[2]

CONCLUSION

Depression is a highly pervasive and complex disease state that can be impacted by comorbid medical and psychiatric conditions, psychosocial factors, as well as medications. While the precise pathophysiology of MDD is still elusive, antidepressant medications have directly targeted monoamine systems for the past half-century, and our understanding is evolving to include other complementary mechanisms. Additionally, research is revealing more about the complexity of the disease and the impact of genetic polymorphisms (both on pathophysiology and impact on pharmacotherapy outcomes). Individual patient characteristics should be considered when selecting antidepressant therapy and monitoring treatment. The goals of treatment should include remission (complete resolution of symptoms) and improved functioning.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is correct when considering the addition of an SSRI to a medication regimen that includes a chronic NSAID prescription?

   A. Combination must be avoided and is contraindicated

   B. Use this combination with caution and monitor patient closely

   C. Combination is associated with enhanced antidepressant efficacy

   D. Combination is associated with increased risk for clot formation

2. Multiple agents with novel mechanisms of action are under investigation or approved for depression. The agent FDA approved for treatment of postpartum depression is:

   A. Brexpiprazole

   B. Samidorphan

   C. Esketamine

   D. Brexanolone

3. Which of the following antidepressants does NOT inhibit reuptake of serotonin?

   A. Mirtazapine

   B. Vilazodone

   C. Vortioxetine

   D. Trazodone

4. According to the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study, which of the following are associated with increased remission rates?

   A. Use of concurrent cognitive behavioral therapy

   B. Achieving high dose

   C. Partial response at 4 days

   D. Switching to different class

5. Choose the most appropriate option for a 68-year-old patient with a history of coronary artery disease taking metoprolol and simvastatin?

   A. Fluoxetine

   B. Fluvoxamine

   C. Sertraline

   D. Nortriptyline

6. In a patient who has successfully achieved remission following the acute phase of treatment, which of the following is the most important factor to consider regarding the decision as to how long treatment should be continued?

   A. Prescription copayment cost

   B. Risk of depressive recurrence

   C. Brand name product availability

   D. Caregiver preference

7. For a patient with history of antidepressant induced sexual dysfunction, which agent is least likely to cause this medication adverse reaction?

   A. Bupropion

   B. Paroxetine

   C. Amitriptyline

   D. Phenelzine

8. In a patient experiencing a treatment refractory major depressive episode, which of the following steps should be confirmed prior to concluding their symptoms are not responding to treatment?

   A. Adequate dose for adequate duration

   B. Adherence to prescribed regimen

   C. Proper monitoring of response

   D. All the above

9. To meet criteria for a major depressive episode (MDE), the patient must exhibit the following symptoms according to the *DSM-5*:

   A. Depressed mood most of the day every day for at least 1 week

   B. At least four of the symptoms as listed in the *DSM-5* for MDE

   C. Impairment in some area of functioning (eg, social, occupational)

   D. History of “switch” into mania following antidepressant treatment

10. Which of the following scenarios is considered a pharmacokinetic medication interaction, instead of a pharmacodynamic medication interaction?

    A. Fluoxetine taken with tamoxifen decreases active metabolite levels

    B. Fluoxetine taken with phenelzine leads to serotonin syndrome

    C. Fluoxetine taken with ibuprofen increases risk of bleeding

    D. Fluoxetine taken with hydrochlorothiazide increases risk of hyponatremia

11. If serotonin syndrome is suspected in a patient being treated with antidepressants, which of the following is the most likely symptom that should be identified?

A. Clonus

B. Asterixis

C. Priapism

D. None of the above

12. When considering next-step antidepressant treatment in a patient who has not achieved full remission, which of the following approaches are supported by the evidence, according to the British Association of Psychopharmacology (BAP) guidelines and the STAR*D trial?

    A. Switch antidepressant

    B. Augment antidepressant

    C. All the above

    D. None of the above

13. A patient taking tranylcypromine should completely avoid which of the following?

    A. Cheese pizza from commercial chains

    B. Apple juice

    C. Sour cream

    D. Prosciutto

14. Which of the following antidepressants have been associated with sustained elevated blood pressure that requires close monitoring during treatment and possible dose adjustments?

    A. Desvenlafaxine

    B. Venlafaxine

    C. Levomilnacipran

    D. All the above

15. When assessing a patient with new onset symptoms of depression, which of the following medications has a clear mechanism as well as evidence to support a high rate of treatment associated depression?

    A. Varenicline

    B. Tetrabenazine

    C. Metoprolol

    D. Sumatriptan

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Use of NSAIDs with antidepressants is not contraindicated with antidepressants. Use of chronic daily NSAIDs should be approached with caution and monitoring due to increased risk of bleeding. NSAIDs may be associated with a higher rate of depression. NSAIDs do not increase risk of clot formation, rather increase risk of bleeding (see Tables 88-10 and 88-11).

2. **D.** Brexpiprazole is a second-generation antipsychotic approved for adjunctive treatment of MDD. Samidorphan is an opioid receptor antagonist. Esketamine is approved for treatment resistant depression. Only brexanolone is seeking FDA approval for treatment of postpartum depression (see Table 88-6).

3. **A.** Mirtazapine does not inhibit the serotonin transporter. Vilazodone, vortioxetine, and trazodone all inhibit the reuptake of serotonin via the transporter in addition to other mechanisms (see Table 88-4).

4. **B.** Patients who achieved remission in STAR*D were on higher average doses of medication. Outcomes regarding cognitive behavioral therapy were limited due to lack of power to analyze this group. Partial response at 2 weeks (not 4 days) was predictive of remission. There were no differences between agents in the switch arm regarding response rates.

5. **C.** Fluoxetine may significantly increase metoprolol levels due to inhibition of CYP2D6 resulting in bradycardia or hypotension. Fluvoxamine may significantly increase levels of simvastatin due to inhibition of CYP3A4. Sertraline does not have significant interactions with metoprolol or simvastatin. Nortriptyline and other TCAs are not recommended in patients over 65 years of age due to anticholinergic effects and may have negative cardiac effects in patients post-MI (see Tables 88-9 and 88-10).

6. **B.** Prescription cost may negatively impact adherence, but should not be a factor in considering continuation of antidepressant treatment. Cost of medication should be considered when initiating treatment to ensure a feasible plan for a patient. Risk of recurrence is the most important factor when determining whether to continue treatment. Caregiver input regarding severity of illness and resolution of symptoms is important in determining response to treatment. Brand name products are no more beneficial than generic products and should not drive treatment decisions.

7. **A.** Bupropion is the only agent listed that is not associated with sexual adverse effects.

8. **D.** All listed factors are important to assess prior to adjusting therapy due to nonresponse.

9. **C.** Depressed mood for most of the day must last for at least 2 weeks. At least five symptoms must be present. History of switch into mania would be suggestive of bipolar disorder not MDE. Patients must have impairment in functioning (see Table 88-2).

10. **A.** Fluoxetine has a pharmacokinetic interaction with tamoxifen as it inhibits metabolism of CYP2D6 that prevents conversion of tamoxifen to its active metabolite. When taken with phenelzine, both agents increase serotonin levels via different mechanisms. When taken with ibuprofen, both agents increase risk of bleeding via different mechanism. When taken with hydrochlorothiazide, both agents can cause hyponatremia via different mechanisms (see Tables 88-9 and 88-10).

11. **A.** Only clonus is associated with serotonin syndrome. Asterixis would be associated with liver failure. Priapism is a rare side effect of trazodone. Trazodone does increase serotonin; however, priapism is not associated with serotonin syndrome.

12. **C.** There were no statistically significant differences between the switch arm and the augmentation arm in the STAR*D trial. Patients with partial response were more likely to choose augmentation. BAP guidelines recommend switching antidepressants if there are troublesome side effects or no improvement in symptoms and augmenting for partial/insufficient response.

13. **D.** Pizza from most commercial chains have low levels of tyramine along with apple juice and sour cream. Prosciutto and other dry aged meats have high tyramine levels and should be avoided completely (see Table 88-5).

14. **D.** All SNRIs are associated with sustained elevated blood pressure and all agents listed are SNRIs.

15. **B.** Varenicline, metoprolol, and sumatriptan have been inconsistently associated with increased risk of depression. Risk is confounded by other variables in studies and has not been clearly linked to mechanism for all agents. Tetrabenazine depletes presynaptic vesicles of monoamines and has a black box warning for treatment associated depression.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 89: Bipolar Disorder

Jordan Cooler Haygood; Shannon J. Drayton

KEY CONCEPTS

KEY CONCEPTS

① Bipolar disorder is a cyclic mental illness with recurrent mood episodes that occur over a person's lifetime. The symptoms, course, severity, and response to treatment differ among individuals.

② Bipolar disorder is likely caused by genetic factors, environmental triggers, and the dysregulation of neurotransmitters, neurohormones, and second messenger systems in the brain.

③ Clinicians should obtain a detailed history, including medical history and substance use history, to expedite the diagnosis and treatment of bipolar disorder.

④ Bipolar disorder is a complex psychiatric illness with significant morbidity and mortality. Suicidal thoughts and behaviors are common in individuals with bipolar disorder and need to be managed with medical and therapeutic interventions.

⑤ The goal of therapy for bipolar disorder should be to improve an individual's functioning by reducing mood episodes. This is accomplished by maximizing adherence to therapy and limiting medication adverse effects.

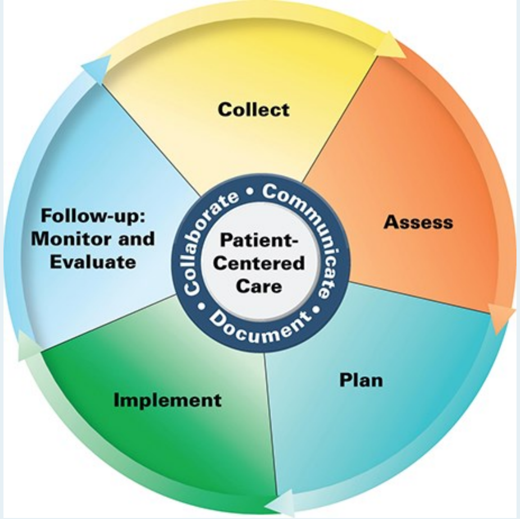
⑥ Patients and family members should be educated about bipolar disorder and treatments. Long-term monitoring and adherence to treatment are primary factors in achieving disease stabilization.

⑦ Lithium, valproate, and second-generation antipsychotics are the mainstays of treatment for different phases of bipolar disorder, acting as primary mood stabilizers. When individuals with bipolar disorder present with an acute mood episode (eg, depressed episode, manic episode or mixed state) despite a primary mood stabilizer, adjunctive medications are considered to target the specific mood state or subtype. These medications can often be tapered once the acute episode has resolved and euthymia is reached. Baseline and follow-up laboratory tests are required for most medications used for bipolar disorder to monitor for adverse effects.

⑧ Some individuals can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents during an acute mood episode. Adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized, if possible. These agents may include benzodiazepines, additional mood stabilizers, antipsychotics, and/or antidepressants.

PATIENT CARE PROCESS

Patient Care Process for Bipolar Disorder



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, sex, pregnancy status)

- Patient psychiatric, medical, social, and family history
- Current medications and prior medication use
- Current and past sleep habits/patterns
- Objective data
    - BP, heart rate, height, weight, and body mass index (BMI)
    - Laboratory test (eg, serum electrolytes, serum creatine [SCr], liver function tests [LFTs], thyroid stimulating hormone [TSH], urine drug screen [UDS])
    - Rating scale scores (eg, Young Mania Rating Scale [YMRS], Hamilton Depression Rating Scale (HDRS or HAM-D), Patient Helath Questionnaire 9 [PHQ-9])

Assess

- Presence of hypomania, mania, or depression
- Adherence to medication regimen
- Appropriateness and effectiveness of current medication regimen
- Serum concentration of medication if appropriate (eg, lithium)
- Current medications that may contribute to or worsen mania or depression
- Suicidality
- Current sleep patterns
- If no response to current medication regimen, reassess diagnosis

Plan*

- If exhibiting euthymia, continue current regimen if appropriate
- If exhibiting mania symptoms, immediately discontinue the antidepressant, optimize regimen, and consider the short-term use of benzodiazepine (see Table 89-4)
- If exhibiting depressive symptoms, optimize regimen and consider adding an antipsychotic (ie, quetiapine, cariprazine, or lurasidone) (see Table 89-4)
- Lifestyle modifications (eg, nutrition, sleep, exercise, stress reduction)
- Monitor for efficacy and safety of medications (see Table 89-6)
- Treat comorbid psychiatric disease states
- Patient education (eg, purpose of treatment, lifestyle modification, drug therapy)
- Self-monitoring for new mood episodes (eg, daily mood chart) and sleep patterns
- Referrals to other providers when appropriate (eg, psychologist, psychiatrist)

Implement*

- Provide education to patients and their families regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up visits

Follow-up: Monitor and Evaluate

- Patient's psychiatric status (eg, rating scale) and safety (eg, suicidality)
- Mood episodes: Document symptoms on a daily mood chart including life stressors, type of episode, length of episode, and treatment outcome. Monthly and yearly life charts are valuable for documenting patterns of mood cycles
- Suicidal ideation or attempts: 6% to 7% of patients with bipolar disorder die by suicide. Suicide attempts are primarily associated with depressive episodes, mixed episodes with severe depression, or presence of psychosis
- Presence of medication-associated adverse effects should be managed rapidly and vigorously to avoid non-adherence (eg, weight gain, sedation)
- Laboratory tests (see Table 89-6)
- Patient adherence to treatment plan using multiple sources of information and presence of residual symptoms (eg, missing doses of medications is a primary reason for non-response and recurrence of episodes)

Collaborate with patient, caregivers, and other healthcare professionals.

INTRODUCTION

① Bipolar disorder is a common, chronic, and often severe cyclic mood disorder characterized by recurrent fluctuations in mood, energy, and behavior.[1,2] It differs from recurrent major depression, or unipolar depression, in that a manic or hypomanic episode occurs during the course of the illness (see section “Clinical Presentation and Diagnosis”).[1] Bipolar disorder is a lifelong illness with a variable course and requires both non-pharmacologic and pharmacologic treatments for mood stabilization.[1,2]

EPIDEMIOLOGY

The lifetime prevalence of bipolar disorder in the United States is 4.4% with 1% of patients meeting criteria for bipolar I, 1.1% for bipolar II, and 2.4% of patients with subthreshold bipolar disorder (ie, cyclothymia, unspecified bipolar disorder).[3] Similar rates of bipolar I disorder are seen in males and females.[4] Symptom onset for depression, mania, or hypomania in bipolar disorder typically occurs in late adolescence or early adulthood, with approximately one-third to two thirds of patients diagnosed with bipolar disorder experiencing their first episode as a child or adolescent.[2] Depression and mixed presentations may occur more frequently in females.[2,5]

ETIOLOGY AND PATHOPHYSIOLOGY

②The exact etiology of bipolar disorder is unknown but is thought to be influenced by a complex of developmental, genetic, neurobiologic, and psychological factors.[4,6] Many theories have been proposed regarding the pathophysiology of mood disorders. Family, twin, and adoption studies report an increased lifetime prevalence risk of having mood disorders among first-degree relatives of patients with bipolar disorder.[7] Genetic linkage studies suggest that multiple gene loci, such as Calcium Channel, Cardiac Dihydropyridine-Sensitive, Alpha-1 Subunit (*CACNA1C*), and Ankyrin 3 (*ANK3*), may be involved in the heredity of mood disorders.[6] Additionally, recent studies have uncovered that there may be genetic differences driving the manifestations of the bipolar disorder subtypes.[8] Neuroimaging studies indicate that several anatomic regions, primarily the amygdala within the limbic system and the prefrontal cortex, may contribute to functional abnormalities in patients with bipolar disorder.[9] It is suspected that altered synaptic and circuit functioning account for mood and cognitive changes seen in bipolar disorder, rather than the dysfunction of individual neurotransmitters.[9] Environmental or psychological stressors, immunologic factors, and sleep dysregulation are also associated with bipolar disorder and can negatively influence the course of illness.[4,10,11]

CLINICAL PRESENTATION AND DIAGNOSIS

Bipolar disorder is a cyclic mood disorder where patients sequentially experience different types of episodes with or without a period of normal mood (euthymia) between episodes. Individuals with bipolar disorder can have mood fluctuations that continue for months, or after one episode, they can sometimes go years without the recurrence of any type of mood episode. ①The essential feature of bipolar spectrum disorders is a history of mania or hypomania that is not caused by any other medical conditions, substances, or psychiatric disorders.[1] The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) of the American Psychiatric Association (APA) details the present understanding of mood disorders.[1] Bipolar disorder is divided into five subtypes based on the identification of specific mood episodes: bipolar I, bipolar II, cyclothymic disorder, other specified bipolar and related disorder, and unspecified bipolar and related disorder.[1] Table 89-1 defines the mood disorders by type of episode. Specifiers (ie, hypomanic or major depressive episode) can be added to bipolar I and II to reflect the most recent mood state. Comorbid conditions associated with bipolar disorder include, but are not limited to, unhealthy substance use, personality disorders, anxiety disorders, eating disorders, and a higher incidence of several medical conditions.[1,2,4]

TABLE 89-1

Mood Disorders Defined by Episodes

Disorder Subtype	Episode(s)[a]
Major depressive disorder, single episode	Major depressive episode
Major depressive disorder, recurrent	Two or more major depressive episodes
Bipolar I disorder[b]	Manic episode ± major depressive or hypomanic episode
Bipolar II disorder[c]	Major depressive episode + hypomanic episode
Persistent depressive disorder (Dysthymia)	Depressed mood most days for at least 2 years (1 year in children and adolescents)
Cyclothymic disorder[d]	Chronic fluctuations between subsyndromal depressive and hypomanic episodes (2 years for adults and 1 year for children and adolescents)
Unspecified bipolar and related disorder	Mood states do not meet full criteria for any specific disorder in the bipolar and related disorders class

[a] The length and severity of a mood episode and the interval between episodes vary from patient to patient. Manic episodes are usually shorter and end more abruptly than major depressive episodes, and even with treatment episodes may last upwards of 3 months and 5 months, respectively. The average length of untreated manic episodes ranges from 4 to 13 months. Episodes can occur regularly (at the same time or season of the year) and often cluster at 12-month intervals. Females have more depressive episodes than manic episodes, whereas males have a more even distribution of episodes.

[b] For bipolar I disorder, 90% of individuals who experience a manic episode later have multiple recurrent major depressive, manic, or hypomanic episodes alternating with a normal mood state.

[c] Approximately 5% to 15% of patients with bipolar II disorder will develop a manic episode over a 5-year period. If a manic episode develops in a patient with bipolar II disorder, the diagnosis is changed to bipolar I disorder.

[d] Patients with cyclothymic disorder have a 15% to 50% risk of later developing a bipolar I or II disorder.

Data from References 1,12.

CLINICAL PRESENTATION: Major Depressive Disorder[a]

DSM-5 Criteria[b]

At least 2-week period of either depressed mood or loss of interest or pleasure in normal activities, associated with at least five of the following symptoms:

- Depressed, sad mood in adults, can be irritable mood in children
- Decreased interest and pleasure in normal activities
- Decreased or increased appetite, weight loss or weight gain
- Insomnia or hypersomnia
- Psychomotor retardation or agitation
- Decreased energy or fatigue
- Feelings of excessive guilt or worthlessness
- Impaired concentration or indecisiveness
- Recurrent thoughts of death, suicidal thoughts, or attempts

Mania[a]

DSM-5 Criteria[b]

At least 1-week period of abnormally and persistently elevated mood (eg, expansive or irritable) and energy, associated with at least three of the following symptoms (four if the mood is only irritable):

- Inflated self-esteem (grandiosity)
- Decreased need for sleep
- Increased talking (pressure of speech)
- Racing thoughts (flight of ideas)
- Distractibility (poor attention)
- Increased goal-directed activity (socially, at work, or sexually) or psychomotor agitation
- Excessive involvement in activities that are pleasurable but have a high risk for serious consequences (buying sprees, sexual indiscretions, poor judgment in business ventures)

Hypomania[a]

DSM-5 Criteria[b]

At least 4 days of abnormally and persistently elevated mood (eg, expansive or irritable) and energy, associated with at least three of the following symptoms listed under Mania above (four if the mood is only irritable):

[a] Impairment in social or occupational functioning; may include need for hospitalization because of potential self-harm, harm to others, or psychotic symptoms.

[b] The disorder is not caused by a medical condition (eg, hypothyroidism) or substance-induced disorder (eg, antidepressant treatment, other medications), or a substance use disorder. Numerous specifiers are available to further characterize episodes (eg, with mixed features, with anxious distress, with rapid cycling, with melancholic features).

Data from Reference 1.

Diagnostic Difficulty

Episodes of mania or depression may be induced or caused by medical illness, medications, or substance intoxication or withdrawal (refer to Table 89-2 for causes of mania[13-21] and Chapter 88, "Depressive Disorders" for causes of depression). The timely diagnosis and treatment of bipolar disorder may be difficult due to frequent episodes of depression, comorbid conditions, and lack of treatment during periods of elevated mood. A complete medical, psychiatric, and medication history; physical examination; and laboratory testing are important tools to rule out any organic causes of mania or depression.[22] An accurate diagnosis is critical as some psychiatric and neurologic disorders present with mania-like or depressive-like symptoms.[2] Bipolar disorder commonly co-occurs with substance use disorders and may be difficult to diagnose in the presence of cocaine use or other illicit substances (eg, psychostimulants, bath salts, synthetic cannabis).[2] When making the diagnosis of new-onset bipolar disorder, particularly in an older population, clinicians should be aware of secondary causes of mania and depression that may impact the treatment.[23,24]

Schizoaffective disorder, which is essentially a mix between schizophrenia and bipolar disorder or unipolar depression, also presents similarly to bipolar disorder. Patients with schizoaffective disorder have mood episodes, but a primary distinguishing factor from bipolar disorder is the occurence of psychosis between mood episodes during periods of euthymic mood.[1,2] Clinicians must rely on the longitudinal history provided by collateral historians who know the patient well to determine if the patient experiences psychosis between mood episodes. It can be difficult for clinicians to obtain a full psychiatric history on individuals presenting with manic or psychotic symptoms, thus making schizoaffective disorder difficult to differentiate from bipolar disorder.[2] Schizoaffective disorder, bipolar type is best treated with antipsychotics with or without a mood stabilizer as maintenance therapy.

Course of Illness

③ Bipolar disorder is frequently not recognized or treated for many years because of its initial fluctuating course with subsyndromal symptoms of depression, irritability, and hypomania that build up gradually in intensity. Though the overall average age of onset falls within the early 20s, patients typically experience delays averaging 8 years after the index mood episode until appropriate medication initiation.[2,25] This delay confers a risk of poor social functioning, increased hospitalizations, and a greater likelihood of lifetime suicide attempts.[26] Onset of illness in early childhood, as opposed to onset in early adulthood, tends to be associated with longer delay to treatment initiation, increased mood episodes, rapid cycling, and comorbid psychiatric conditions as well as a stronger family history of mood disorders.[27,28] Gender differences may influence the course of illness, tolerability of medication, and response to treatment. Females are more likely to have increased depressive symptoms, older age of onset, better adherence, complex management in pregnancy, and higher association with physical illness such as thyroid abnormalities. In males, there may be increased incidence of mania and substance use/misuse.[29]

The kindling theory is used to explain how bipolar disorder can progress over one's life and why preventive treatment is imperative. Without effective treatment, episodes can become more frequent, severe, and refractory to treatment.[4,10,30,31,44] Usually, there is a period of euthymia between episodes, but approximately 20% to 30% of patients with bipolar I disorder and 15% with bipolar II disorder have no inter-episode period of euthymia because of mood lability, residual subsyndromal mood symptoms, or a direct switch to the opposite polarity.[1]

Rapid cycling is defined as more than four mood episodes per year and is more common in females and has a lifetime prevalence as high as 25% to 43% in all patients with bipolar disorder.[2,32] Frequent and severe episodes of depression are the most common hallmark of rapid cycling. The use of alcohol, stimulants, and antidepressants, as well as sleep deprivation, hypothyroidism, and seasonal changes, can play a role in rapid cycling.[2,32] Seasonal patterns of mania in the summer and depression during the winter have been observed. Pateints with rapid cycling have a poorer long-term prognosis and often require combination therapies.[1,2]

Fluctuations in hormones and neurotransmitters during the luteal phase of the menstrual cycle, postpartum period, and perimenopause, starting ~10 years before menopause, can precipitate mood changes and increase cycling.[1,2] Evidence supports that females with a history of premenstrual dysphoric disorder (PMDD) diagnosed with bipolar disorder display higher rates of rapid cycling and a greater number of mood episodes.[33] Females with bipolar disorder are at greater risk for relapse into mania or depression during the postpartum period.[2] If a severe mood episode occurs postpartum, there is an increased risk for recurrences during subsequent postpartum periods.[2]

Bipolar disorder is associated with several comorbid psychiatric diagnoses most commonly substance use disorder, anxiety disorder, personality disorder, and impulse control disorders that require careful treatment considerations. Often times, medications utilized to stabilize mood may also be effective in managing comorbidities. Conversely, certain treatment options for comorbidities such as anxiety disorders may further destabilize patients if adequate treatment for mood stability is not first employed. A hierarchical approach should be taken when managing comorbid psychiatric diagnoses.[2]

Alcohol and other substance use or missue is common among patients with bipolar disorder and can have a significant impact on the age of onset, course of the illness, and response to treatment.[2] Substance use disorders have been reported in 33% to 45% of individuals with bipolar disorder.[34,35] Those with substance use disorders are more likely to have an earlier onset of their illness, mixed states, higher rates of relapse, a poorer response to treatment, comorbid personality disorders, increased suicide risk, and more psychiatric hospitalizations.[2] When individuals with bipolar disorder use substances such as alcohol, cannabis, or cocaine during episodes, it can result in further impairment of judgment, poor impulse control, treatment non-adherence, and a worsening of the clinical course. Alcohol and other substance use should be addressed as early as possible in the individual's clinical course to improve outcomes.[2]

④ For those living with bipolar disorder, approximatly one-half of their lifetime is spent with syndromal and subsyndromal symptoms, particularly those with depressive episodes.[2] More than one-half (55%-65%) of patients with bipolar I have some degree of functional disability after the onset of their illness, and approximately 10% to 20% of patients with bipolar disorder have severe impairment in their psychosocial and occupational functioning.[1,22,36] Functional impairment is often more pronounced in patients with depression, a greater number of previous episodes, a longer duration of illness, and lower cognition. In a 1-year longitudinal study in 258 patients with bipolar disorder, two-thirds had four or more mood episodes a year despite comprehensive pharmacologic treatment, and approximately 33.2% of the year was spent being depressed compared with 10.8% of the time in the mania phase.[36]

Compared with the general population, individuals with bipolar disorder have a two-fold higher mortality rate.[37] Suicide attempts occur in one-third to one-half of individuals with bipolar disorder, and approximately 6% to 7% of individuals with bipolar I disorder die by suicide.[2,38] Roughly 43% of patients with bipolar disorder worldwide report suicidal ideation. Many factors are associated with suicide attempts including female sex, depression with a current or more recent episode, previous attempts, and comorbid substance use disorder.[2]

The best predictor for the level of functioning during a person's lifetime is adherence with medication treatment. Medication non-adherence is estimated to occur in 20% to 60% of patients secondary to multiple factors including intolerance of adverse medication effects.[39] Due to failure to recognize the disorder, reluctance to acknowledge it, or poor adherence with treatment, an estimated two-thirds of patients with bipolar disorder do not receive appropriate treatment. Non-adherence with pharmacologic treatment and substance use are major factors in relapse and hospitalizations.[2]

TABLE 89-2

Secondary Causes of Mania

Medical conditions that induce mania

- CNS disorders (eg, brain tumor, strokes, head injuries, subdural hematoma, multiple sclerosis, systemic lupus erythematosus, temporal lobe seizures, Huntington's disease)
- Infections (eg, encephalitis, neurosyphilis, sepsis, human immunodeficiency virus)
- Electrolyte or metabolic abnormalities (eg, calcium or sodium fluctuations, hyperglycemia, or hypoglycemia)
- Endocrine or hormonal dysregulation (eg, Addison's disease, Cushing disease, hyperthyroidism or hypothyroidism, menstruation-related, or pregnancy-related or perimenopausal mood disorders)

Medications or drugs that induce mania

- Alcohol intoxication
- Drug withdrawal states (eg, alcohol, α_2-adrenergic agonists, antidepressants, barbiturates, benzodiazepines, opiates)
- Antidepressants (eg, MAOIs, TCAs, 5-HT and/or NE and/or DA reuptake inhibitors, 5-HT antagonists)
- DA-augmenting agents (CNS stimulants: amphetamines, cocaine, sympathomimetics; DA agonists, releasers, and reuptake inhibitors)
- Hallucinogens (eg, LSD, PCP)
- Cannabis intoxication precipitates psychosis, paranoid thoughts, anxiety, and restlessness
- NE-augmenting agents (eg, α_2-adrenergic antagonists, β-agonists, NE reuptake inhibitors)
- Steroids (eg, anabolic, adrenocorticotropic hormone, corticosteroids)
- Thyroid preparations
- Xanthines (eg, caffeine, theophylline)
- Non-prescription weight loss agents and decongestants (eg, ephedra, pseudoephedrine)
- Herbal products (eg, St. John wort)

Somatic therapies that induce mania

- Bright light therapy
- Deep brain stimulation
- Sleep deprivation

CNS, central nervous system; DA, dopamine; 5-HT, serotonin; LSD, lysergic acid diethylamide; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; PCP, phencyclidine; TCA, tricyclic antidepressant.

Data from References 1,4,13-21.

TREATMENT

Desired Outcomes

⑤ The desired outcome in treating bipolar disorder is to effectively resolve acute manic, hypomanic, and depressive episodes, as well as prevent further episodes, maintain healthy functioning, promote treatment adherence, and minimize medication adverse effects.[2,4] The general principles and goals for the management of bipolar disorder are listed in Table 89-3.

TABLE 89-3

General Principles for the Management of Bipolar Disorder

Goals of treatment

- Eliminate mood episode with complete remission of symptoms (ie, acute treatment)
- Prevent recurrences or relapses of mood episodes (ie, continuation phase treatment)
- Return to baseline psychosocial functioning
- Maximize adherence with therapy
- Minimize adverse effects
- Use medications with the best tolerability and fewest drug interactions
- Minimize polypharmacy when possible
- Treat comorbid substance use and use disorders
- Eliminate alcohol, cannabis, cocaine, amphetamines, and hallucinogens
- Minimize nicotine use and stop caffeine intake at least 8 hours prior to bedtime
- Avoidance of stressors or substances that precipitate an acute episode

Data from References 2,4.

General Approach to Treatment

⑥ Treatment of bipolar disorder must be individualized because the clinical presentation, severity, and frequency of episodes vary widely among patients. Treatment approach should include both non-pharmacologic and pharmacologic strategies.[2] Patients and family members should be educated about bipolar disorder (eg, symptoms, causes, and course) and treatment options. Long-term adherence to treatment is the most important factor in achieving stabilization of the disorder.

⑦ The treatment of bipolar disorder can vary depending on the type of episode the patient is experiencing. Once diagnosed with bipolar disorder, patients should remain on a mood stabilizer (eg, lithium, valproate, or a second-generation antipsychotic) for their lifetime. During acute episodes, medications can be added and then tapered once the patient is stabilized and euthymic. For example, when treating a patient for mania with psychotic features, the patient should be on a mood stabilizer and an antipsychotic. If the antipsychotic is the patient's maintenance therapy, the dose should be increased or perhaps the medication should be changed altogether if the patient's mood becomes manic. If treating a patient for a severe depressive episode, a clinician may need to maximize the dose of the mood stabilizer or add another medication (eg, quetiapine).

Non-pharmacologic Therapy

The basics of non-pharmacologic approaches should address issues of adequate nutrition, sleep, exercise, and stress reduction.[2] Sleep deprivation, high stress, and dietary deficiencies in essential amino acids, fatty acids, vitamins, and minerals can exacerbate mood episodes and result in worse outcomes.[2,40,41] Psychological interventions are aimed at providing individuals with self-management skills and tools for mood regulation. Adjunctive psychosocial interventions are useful for acute depressive episodes and in maintenance and relapse prevention.[2] Evidence-based approaches include: cognitive behavioral therapy (CBT), interpersonal and social rhythm therapy, group psychoeducation, family-focused therapy, and enhanced relapse prevention/individual psychoeducation.[2] Common features of these are providing education about the condition, identifying prodromal warning signs, developing coping strategies, and developing crisis plans.[2]

Pharmacologic Therapy

⑦ Pharmacotherapy is crucial for acute and maintenance treatments of bipolar disorder and includes lithium, valproate, carbamazepine, lamotrigine, first-generation antipsychotics (FGAs), second-generation antipsychotics (SGAs), and adjunctive agents such as antidepressants and benzodiazepines. General treatment guidelines for the acute treatment of mood episodes in patients with bipolar I disorder are listed in Table 89-4.[2,22]

TABLE 89-4

Algorithm and Guidelines for the Acute Treatment of Mood Episodes in Patients with Bipolar I Disorder

Acute Manic or Mixed Episode		Acute Depressive Episode	
General Guidelines		General Guidelines	
- Assess for secondary causes of mania or mixed states (eg, alcohol or drug use) - Discontinue antidepressants - Taper off stimulants and caffeine if possible - Treat substance use - Encourage good nutrition with regular protein and essential fatty acid intake, exercise, adequate sleep, stress reduction, and psychosocial therapy		- Assess for secondary causes of depression (eg, alcohol or drug use) - Taper off antipsychotics, benzodiazepines, or sedative–hypnotic agents if possible - Treat substance use/misuse - Encourage good nutrition with regular protein and essential fatty acid intake, exercise, adequate sleep, stress reduction, and psychosocial therapy	
Hypomania	**Mania**	**Mild-to-Moderate Depressive Episode**	**Severe Depressive Episode**
- **First**, optimize current mood stabilizer if non-adherence is suspected or initiate mood-stabilizing medication: lithium,[a] valproate,[a] carbamazepine,[a] or SGAs - Consider adding a benzodiazepine (eg, lorazepam or clonazepam) for short-term adjunctive treatment of agitation or insomnia if needed - Oxcarbazepine is an alternative medication treatment option - **Second**, if response is inadequate, consider a two-drug combination: - Lithium[a] **plus** an antiseizure medication or an SGA - antiseizure medication **plus** an antiseizure medication or SGA	- **First**, optimize the previously prescribed mood stabilizer or medication regimen if non-adherence suspected or initiate new mood-stabilizing two- or three-drug combinations (lithium,[a] valproate,[a] or SGA) **plus** a benzodiazepine (eg, lorazepam or clonazepam) and/or antipsychotic for short-term adjunctive treatment of agitation or insomnia; lorazepam is recommended for catatonia - Do not combine antipsychotics - Alternative options: carbamazepine[a]; if patient does not respond or tolerate, consider oxcarbazepine - **Second**, if response is inadequate, consider a three-drug combination: - Lithium[a] **plus** an antiseizure medication **plus** an antipsychotic, or - antiseizure medication **plus** an antiseizure medication **plus** an antipsychotic - **Third**, if response is inadequate, consider ECT for mania with psychosis or catatonia[b] or add clozapine for treatment-refractory illness	- **First**, initiate and/or optimize mood-stabilizing medication: lithium,[a] quetiapine, lurasidone - Alternative antiseizure medications: lamotrigine,[c] valproate[a]; antipsychotics: fluoxetine/olanzapine combination	- **First**, optimize current mood stabilizer if non-adherence is suspected or initiate a new mood-stabilizing medication: lithium,[a] quetiapine, or lurasidone - Alternative fluoxetine/olanzapine combination - If psychosis is present, initiate an antipsychotic in combination with above - Do not combine antipsychotics - Alternative antiseizure medications: lamotrigine,[c] valproate[a] - **Second**, if response is inadequate, consider carbamazepine[a] or adding antidepressant[d] - **Third**, if response is inadequate, consider a three-drug combination: - Lithium **plus** lamotrigine[c] **plus** an antidepressant[d] - Lithium **plus** quetiapine **plus** antidepressant[d] - **Fourth**, if response is inadequate, consider ECT for treatment-refractory illness and depression with psychosis or catatonia[b]

ECT, electroconvulsive therapy; SGA, second-generation antipsychotic.

[a] Use standard therapeutic serum concentration ranges if clinically indicated; if partial response or breakthrough episode, adjust dose to achieve higher serum concentrations without causing intolerable adverse effects; lithium, SGAs, and/or lamotrigine are preferred over valproate and carbamazepine for bipolar depression.

[b] ECT is used for severe mania or depression during pregnancy and for mixed episodes; prior to treatment, antiseizure medication, lithium, and benzodiazepines should be tapered off to maximize therapy and minimize adverse effects.

[c] Lamotrigine is not approved for the acute treatment of depression, and the dose must be started low and slowly titrated up to decrease adverse effects if used for maintenance therapy. Lamotrigine may be initiated during acute treatment with plans to transition to this medication for long-term maintenance. A drug interaction and a severe dermatologic rash can occur when lamotrigine is combined with valproate (ie, lamotrigine doses must be halved from standard dosing titration).

[d] Controversy exists concerning the use of antidepressants, and they are often considered third line in treating acute bipolar depression, except in patients with no recent history of severe acute mania or potentially in

bipolar II patients.

Data from References 2,22.

Product information, dosing, and administration of agents used in the treatment of bipolar disorder are found in Table 89-5.

TABLE 89-5

Products, Dosage and Administration, and Clinical Use of Agents Used in the Treatment of Bipolar Disorder

Drug (Brand Name)	Initial Dosing	Usual Dosing; Special Population Dosing	Comments
Lithium salts			
Lithium carbonate (Eskalith)[a,b] (Eskalith CR) (Lithobid) Lithium citrate (Cibalith-S)[a,b]	300 mg twice daily	900-2,400 mg/day in two to four divided doses, preferably with meals Renal impairment: lower doses required with frequent serum monitoring. There is wide variation in the dosage needed to achieve therapeutic response. Trough serum lithium concentration (ie, 0.6-1.2 mEq/L [mmol/L] for maintenance therapy and 0.8-1.2 mEq/L [mmol/L] for acute mood episodes taken 12 hours after the last dose)	Use alone or in combination with other medications (eg, valproate, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment
Antiseizure medications			
Divalproex sodium (Depakote)[a] (Depakote ER) Valproic acid[a] (Depakene) Valproate sodium (Depacon)	250-500 mg twice daily A loading dose of divalproex (20-30 mg/kg/day) can be given	750-3,000 mg/day (20-60 mg/kg/day) given once daily or in divided doses Titrate to clinical response Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, carbamazepine, antipsychotics) for the acute treatment of mania and for maintenance treatment Use caution when combining with lamotrigine because of potential drug interaction
Lamotrigine (Lamictal)[b]	25 mg daily	50-400 mg/day in divided doses. Dosage should be slowly increased (eg, 25 mg/day for 2 weeks, then 50 mg/day for weeks 3 and 4, and then 50-mg/day increments at weekly intervals up to 200 mg/day) Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, carbamazepine) for long-term maintenance treatment for bipolar I disorder
Carbamazepine (Equetro)[a] (Tegretol) (Epitol) (Tegretol-XR) (Carbatrol)	200 mg twice daily	200-1,800 mg/day in two to four divided doses Titrate to clinical response Dose adjustment needed with hepatic impairment	Use alone or in combination with other medications (eg, lithium, valproate, antipsychotics) for the acute and long-term maintenance treatment of mania or mixed episodes for bipolar I disorder. APA guidelines recommend reserving it for patients who were unable to tolerate or who have inadequate response to lithium or valproate Extended-release tablets should be swallowed whole and not be broken or chewed "Carbatrol" capsules can be opened and contents sprinkled over food
Oxcarbazepine (Trileptal)	300 mg twice daily	300-1,200 mg/day in two divided doses Titrate based on clinical response Dose adjustment required with severe renal impairment	Use after patients have failed treatment with carbamazepine or have intolerable adverse medication effects May have fewer adverse effects and be better tolerated than carbamazepine
Atypical antipsychotics			
Aripiprazole (Abilify)[a,b] (Abilify Maintena)[b]	10-15 mg daily	10-30 mg/day once daily	

Asenapine (Saphris)[b]	5-10 mg twice daily sublingually	5-10 mg twice daily sublingually	
Cariprazine (Vraylar)[a]	1.5 mg daily	3-6 mg daily	
Lurasidone (Latuda)[c]	20 mg daily	20-120 mg daily with food	
Olanzapine (Zyprexa)[a,b] (Zyprexa Zydis)	2.5-5 mg twice daily	5-20 mg/day once daily or in divided doses	
Olanzapine and fluoxetine (Symbyax)[c]	6 mg olanzapine and 25 mg fluoxetine daily	6-12 mg olanzapine and 25-50 mg fluoxetine daily	
Quetiapine)Seroquel[a,b]	50 mg twice daily	50-800 mg/day in divided doses or once daily when stabilized	
Risperidone (Risperdal)[a] (Risperdal M-Tab) (Risperdal Consta)[b]	0.5-1 mg twice daily	0.5-6 mg/day once daily or in divided doses	
Ziprasidone (Geodon)[a]	40-60 mg twice daily	40-160 mg/day in divided doses	
Benzodiazepines			
Various	Dosage should be slowly adjusted up and down according to response and adverse effects	Use in combination with other medications (eg, antipsychotics, lithium, valproate) for the acute treatment of mania or mixed episodes Use as a short-term adjunctive sedative–hypnotic agent	

[a] FDA-approved for acute mania.

[b] FDA-approved for maintenance.

[c] FDA-approved for acute bipolar depression.

FDA-approved agents may be used as monotherapy in various phases of the illness as noted in table footnotes.

Data from References 42,47.

7 The term *mood stabilizer* is often used to describe the class of medications used for stabilizing the patient's mood and as maintenance therapy for the prevention of mood fluctuations (eg, mania or depression). However, this term may not be accurate, as some medications are more effective for acute mania, some for the depressive episode, and others for the maintenance phase. Table 89-5 provides the US Food and Drug Administration (FDA) approval status for medications used.

Combination therapies (eg, lithium plus valproate or carbamazepine, lithium, or valproate plus an SGA) can provide better acute response and long-term prevention of relapse and recurrence than monotherapy in some patients with bipolar disorder.[48] The majority of patients hospitalized for an acute episode will be initiated on combination therapy, and after acute symptoms resolve, the medication regimen should be simplified as much as possible.

Several guidelines and algorithms have been published regarding bipolar disorder treatment, based on the best available data and expert consensus. The Canadian Network for Mood and Anxiety Treatments (CANMAT) and International Society for Bipolar Disorders (ISBD) published updated treatment guidelines in 2018.[2] In addition, an international task force of the World Federation of

Societies of Biological Psychiatry (WFSBP) has published guidelines for maintenance of mania, depression, and mixed episodes.[49-52]

An example treatment algorithm for acute mood episodes in adult patients with bipolar I disorder is listed in Table 89-4. The selection of treatment for acute mood episodes (eg, mania or depression) and for maintenance treatment should be individualized. Treatment plans should be based on patient-specific characteristics, comorbid psychiatric and medical conditions, consideration of drug interactions, and avoidance of adverse effects.[2]

Lithium

Lithium was first used in 1949 as a treatment for mania and was approved in 1972 in the United States for the treatment of acute mania and for maintenance therapy. Despite numerous investigations into the biologic and clinical properties of lithium, there is no unified theory for its mechanism of action[42]; however, it is thought to modulate neurotransmission at both the neuronal and intracellular levels, and chronic administration may modulate gene expression and have neuroprotective effects.[53] Lithium is a monovalent cation that is rapidly absorbed, and widely distributed with no protein binding. It is also not metabolized and is excreted unchanged in the urine and in other body fluids.[42]

Efficacy

Lithium is considered a first-line agent for acute mania and maintenance treatment of bipolar I and II disorders.[2] Early placebo-controlled studies with lithium reported up to a 78% response rate in aborting an acute manic or hypomanic episode, but more recent studies suggest a slower onset of action and more moderate effectiveness when compared with other agents.[54,55]

Recent treatment guidelines recommend lithium as a second-line agent for acute bipolar II depression based on conflicting efficacy in clinical studies comparing lithium alone to various alternative treatments or placebo.[2] In placebo-controlled studies in bipolar depression, lithium has been found to have efficacy, but there can be a 6- to 8-week delay for its antidepressant effects.[55] A potential rationale for lithium's reduced efficacy in certain trials may be subtherapeutic serum levels in the lithium treatment arm.[2] Lithium also produces a antisuicidal actions in patients with bipolar disorder which has been demonstrated consistently in clinical studies.[56] Relapse can be reduced with the combination of lithium and other medications such as valproate, carbamazepine, lamotrigine, and antipsychotics.[55] Abrupt discontinuation or non-adherence with lithium therapy can increase the risk of relapse.[55]

Adverse Effects

Adverse effects related to lithium use can be divided into three categories: those that occur early in therapy but are generally innocuous and transient, those that are not dose-related occurring with long-term treatment, and toxic effects that occur with high serum concentrations.[42]

Initial gastrointestinal (GI) and central nervous system (CNS) adverse effects are often dose-related and are worse at peak serum concentrations, approximately 1-2 hours post-dose. GI side effects are often associated with lithium initiation and may include anorexia, nausea, vomiting, abdominal pain, and diarrhea.[57] Standard approaches for minimizing adverse effects include lowering the dose, taking doses with food, using extended-release products, and trying once-daily dosing at bedtime.[57] Diarrhea can sometimes be managed by switching from tablet or capsule formulation to liquid formulation.[57] Diarrhea produced by lithium is commonly an osmotic diarrhea, and therefore switching to a formulation that clears the gut quickly can ameliorate symptoms.

A benign fine hand tremor can be evident in many patients while a course hand tremor may be a sign of toxicity.[2,54] Strategies to reduce the fine tremor include standard approaches (eg, switch to long-acting preparation, lower dose if possible) or adding a β-adrenergic antagonist (eg, propranolol 20-120 mg/day).[57]

Polydipsia with polyuria associated with or without nephrogenic diabetes insipidus (DI) can occur in patients treated with lithium. About 20% to 40% of patients will develop nephrogenic DI soon after treatment initiation.[2] Patients who develop uncontrolled nephrogenic DI may experience fluid and electrolyte disturbances.[58] Nephrogenic DI will persist in about 10% to 25% of patients on continued treatment and typically is reversible with discontinuation of lithium.[42] Other nonspecific renal effects may be seen with lithium treatment, including proteinuria, distal renal tubular acidosis, and reduced glomerular filtration rate.[58]

Both overt (8%-19%) and subclinical (23%) hypothyroidism can occur in patients treated with lithium, occurring more frequently in females than males.[54,57] Supplemental exogenous thyroid hormone (ie, levothyroxine) can be added to the patients' regimen. If lithium is discontinued, the need for the exogenous thyroid hormone should be reassessed because hypothyroidism can be reversible.[2]

Lithium can cause a variety of benign and reversible cardiac effects, particularly T-wave depression in up to 16% to 33% of patients, atrioventricular block, and bradycardia.[42,59] If a patient has significant preexisting cardiac disease, consultation with a cardiologist and an electrocardiogram (ECG) is recommended at baseline and during lithium therapy.[25]

Other adverse effects associated with lithium include acne and folliculitis (1%), reversible leukocytosis, and weight gain.[42] Approximately 20% of patients gain greater than 10 kg [22 lbs] which can be related to fluid retention, the consumption of high-calorie beverages as a result of polydipsia, or a decreased metabolic rate because of hypothyroidism.[60]

Toxicity

Lithium is an extremely toxic medication if accidentally or intentionally taken in overdose. Lithium toxicity usually occurs with blood levels greater than 1.5 mEq/L (mmol/L), but older patients may experience toxicity at lower levels.[42] Severe lithium intoxication occurs when concentrations are higher than 2 mEq/L (mmol/L), and there is a worsening in several key symptoms: *GI* (eg, vomiting, diarrhea, or incontinence), *coordination* (eg, fine to coarse hand tremor, unstable gait, slurred speech, and muscle twitching), and *cognition* (eg, poor concentration, drowsiness, disorientation, confusion, apathy, and coma).[4,54] There have been several reports of seizures, cardiac dysrhythmias, permanent neurologic impairments with ataxia and memory deficits, and kidney damage with reduced glomerular filtration rate after lithium intoxication.[54]

Situations that predispose patients to lithium toxicity include sodium restriction, dehydration, vomiting, diarrhea, older than 50 years, heart failure, cirrhosis, and drug interactions that decrease lithium clearance. Heavy exercise, sauna baths, hot weather, and fever can promote sodium loss.[61,62] Patients should be cautioned to maintain adequate sodium and fluid intake (2.5-3 qt [~2.5-3 L] per day of fluids) and to avoid the excessive use of alcohol, coffee, tea, cola, and other caffeine-containing beverages.

If lithium toxicity is suspected, the person should go to an emergency room to be monitored and lithium should be discontinued.[22] Gastric lavage and IV fluids may be needed, and the patient should be monitored for fluid balance, renal/electrolyte status, and neurologic changes. Activated charcoal is not useful in the setting of lithium toxicity due to its electrically charged nature. Serial serum concentrations should be obtained as renal excretion of lithium may reach a ceiling.[57] Intensive care unit measures should be considered in patients experiencing severe symptoms of toxicity including dysrhythmias, obtundation, or complex fluid/electrolyte imbalances. Hemodialysis may be considered in lithium-naïve patients who may be presenting in an acute overdose situation when lithium concentrations equal or exceed 4 mEq/L (mmol/L) regardless of clinical status or in patients previously taking lithium when lithium concentrations are 2.5 mEq/L (mmol/L) or greater and moderate-to-severe neurologic toxicity, or as clinically indicated.[63] If hemodialysis is initiated, it should be continued until the lithium concentration is below 1 mEq/L (mmol/L) with levels being taken 8 hours after the last dialysis to account for lithium redistribution leading to additional increases in serum levels.

Chronic lithium toxicity may be uncommonly associated with interstitial nephris. Patients exposed to elevated serum levels of lithium and longer-term use may be at risk.[58] Risk of chronic kidney disease is low and mimic, which is seen in the general population.[64]

Drug-Drug Interactions

Thiazide diuretics, non-steroidal anti-inflammatory drugs, cyclooxygenase-2 inhibitors, angiotensin-converting enzyme inhibitors, and salt-restricted diets can elevate lithium levels.[42] Neurotoxicity can occur when lithium is combined with antipsychotics, metronidazole, methyldopa, and phenytoin.[42] Combining lithium with non-dihydropyridine calcium channel blockers is not recommended because of reports of decreased lithium levels and neurotoxicity.[42] Analgesics such as acetaminophen or aspirin and loop diuretics are less likely to interfere with lithium clearance. Caffeine and theophylline can enhance the renal elimination of lithium. Because lithium has no effect on hepatic metabolizing enzymes, it has fewer drug-drug interactions compared with carbamazepine, oxcarbazepine, and valproate.

Dosing and Administration

Lithium dosing depends on the patient's age and weight, tolerance to adverse effects, and the acuity of the illness. Lithium therapy is usually initiated with low-to-moderate doses (600 mg/day) for prophylaxis and higher doses (900-1,200 mg/day) for acute mania, using a two- to-three-times daily dosing regimen.[42] The dose should be adjusted based on the steady-state serum concentration and clinical picture of the patient. Immediate-release lithium preparations should be given in two or three divided daily doses, whereas extended-release products can be given once or twice daily. In clinical practice many clinicians dose the immediate-release and extended-release preparations once daily. It is best to initially begin a patient on divided dosing, but once stabilized many patients are able to switch to once-daily dosing without decompensating.[54,65]

Lithium levels should be monitored for efficacy and to guide dosing. In general, lithium serum concentrations should be maintained between 0.6 and 1 mEq/L (mmol/L) for maintenance therapy.[2,55] Lithium levels are considered to be at steady-state at approximately day 5, and serum samples should be drawn 12 hours post dose. When being used acutely, some clinicians may order lithium levels prior to reaching steady-state to more closely monitor the therapy. Once a desired serum concentration has been achieved, levels should be drawn in 2 weeks. Maintenance lithium serum concentrations are usually measured every 3 months but can be adjusted to every 6 months for stabilized patients, or more frequently if clinically indicated (eg, patients with frequent mood episodes).[2] Lithium clearance rates increase by 50% to 100% during pregnancy and return to normal postpartum. Thus, lithium levels should be determined monthly during pregnancy and weekly the month before delivery. At delivery, rapid fluid changes can significantly increase lithium levels; thus, a reduction to pre-pregnancy lithium doses and adequate hydration are recommended.[22]

The recommended guidelines for baseline and routine laboratory testing for lithium are listed in Table 89-6. A therapeutic trial for outpatients should last a minimum of 4 to 6 weeks with lithium serum concentrations of 0.6 to 1.2 mEq/L (mmol/L). Antidepressant efficacy may take longer. Acutely manic patients can require serum concentrations of 1 to 1.2 mEq/L (mmol/L), and some need up to 1.5 mEq/L (mmol/L) to achieve a therapeutic response. Although serum concentrations less than 0.6 mEq/L (mmol/L) may be associated with higher rates of relapse, some patients can do well at 0.4 to 0.7 mEq/L (mmol/L).[55] For bipolar prophylaxis in older patients, serum concentrations of 0.4 to 0.6 mEq/L (mmol/L) are recommended because of increased sensitivity to adverse effects with up to 0.8 mEq/L (mmol/L) being beneficial for acute episodes.[2]

TABLE 89-6

Guidelines for Baseline and Routine Laboratory Tests and Monitoring for Patients with Bipolar Disorder Taking Mood Stabilizers

	Baseline: Physical Examination and General Chemistry[a]	Hematologic Tests[b]		Metabolic Tests[c]		Liver Function Tests[d]		Renal Function Tests[e]		Thyroid Function Tests[f]		Serum Electrolytes[g]		Dermatologic[h]		Pharmacogenomic Testing
	Baseline	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline	6-12 months	Baseline
SGAs[i]	X			X	X											
Carbamazepine[j]	X	X	X			X	X	X				X	X	X	X	X
Lamotrigine[k]	X													X	X	
Lithium[l]	X	X	X	X	X			X	X	X	X	X	X	X	X	
Oxcarbazepine[m]	X											X	X			X
Valproate[n]	X	X	X	X	X	X	X							X	X	

SGAs, second-generation antipsychotics.

[a] Screen for drug use and serum pregnancy.

[b] Complete blood cell count (CBC) with differential and platelets.

[c] Fasting glucose, serum lipids, and weight.

[d] Lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, total bilirubin, and alkaline phosphatase.

[e] Serum creatinine, blood urea nitrogen, urinalysis, urine osmolality, and specific gravity.

[f] Triiodothyronine, total thyroxine, thyroxine uptake, and thyroid-stimulating hormone.

[g] Serum sodium.

[h] Rashes, hair thinning, and alopecia.

[i] Second-generation antipsychotics: Monitor for increased appetite with weight gain (primarily in patients with initial low or normal body mass index); monitor closely if rapid or significant weight gain occurs during early therapy; cases of hyperlipidemia and diabetes reported.

[j] Carbamazepine: Manufacturer recommends CBC and platelets (and possibly reticulocyte counts and serum iron) at baseline and that subsequent monitoring be individualized by the clinician (eg, CBC, platelet counts, and liver function tests every 2 weeks during the first 2 months of treatment, and then every 3 months if normal). Monitor more closely if patient exhibits hematologic or hepatic abnormalities or if the patient is receiving a myelotoxic drug; discontinue if platelets are <100,000/mm^3 (100 × 10^9/L), if white blood cell (WBC) count is <3,000/mm^3 (3 × 10^9/L), or if there is evidence of bone marrow suppression or liver dysfunction. Serum electrolyte levels should be monitored in older patients or those at risk for hyponatremia. Carbamazepine interferes with some pregnancy tests.

[k] Lamotrigine: If renal or hepatic impairment, monitor closely and adjust dosage according to manufacturer's guidelines. Serious dermatologic reactions have occurred within 2 to 8 weeks of initiating treatment and are more likely to occur in patients receiving concomitant valproate, with rapid dosage escalation, or using doses exceeding the recommended titration schedule.

[l] Lithium: Obtain baseline electrocardiogram for patients older than 40 years or if preexisting cardiac disease (benign, reversible T-wave depression can occur). Renal function tests should be obtained every 2 to 3 months during the first 6 months, and then every 6 to 12 months; if impaired renal function, monitor 24-hour urine volume and creatinine every 3 months; if urine volume>3 L/day, monitor urinalysis, osmolality, and specific gravity every 3 months. Thyroid function tests should be obtained once or twice during the first 6 months, and then every 6 to 12 months; monitor for signs and symptoms of hypothyroidism; if supplemental thyroid therapy is required, monitor thyroid function tests and adjust thyroid dose every 1 to 2 months until thyroid function indices are within normal range, and then monitor every 3 to 6 months.

[m] Oxcarbazepine: Hyponatremia (serum sodium concentrations <125 mEq/L [mmol/L]) has been reported and occurs more frequently during the first 3 months of therapy; serum sodium concentrations should be monitored in patients receiving drugs that lower serum sodium concentrations (eg, diuretics or drugs that cause inappropriate antidiuretic hormone secretion) or in patients with symptoms of hyponatremia (eg, confusion, headache, lethargy, malaise). Hypersensitivity reactions have occurred in approximately 25% to 30% of patients with a history of carbamazepine hypersensitivity and require immediate discontinuation.

[n] Valproate: Weight gain reported in patients with low or normal body mass index. Monitor platelets and liver function during first 3 to 6 months if evidence of increased bruising or bleeding. Monitor closely if patients exhibit hematologic or hepatic abnormalities or in patients receiving drugs that affect coagulation, such as aspirin or warfarin; discontinue if platelets are <100,000/mm^3 (100 × 10^9/L) or if prolonged bleeding time. Pancreatitis, hyperammonemic encephalopathy, polycystic ovary syndrome, increased testosterone, and menstrual irregularities have been reported; not recommended during first trimester of pregnancy due to risk of neural tube defects.

Data from References 42-46,66,67.

Antiseizure Medications

Antiseizure medications (ADMs) are widely prescribed for the treatment of bipolar disorder with varying degrees of evidence. Divalproex sodium (also known as sodium valproate) was marketed in 1995 and is FDA-approved only for the treatment of acute manic or mixed episodes. However, it is commonly used in clinical practice as maintenance monotherapy for bipolar disorder. Limited data support its use in acute bipolar depression.[2] Carbamazepine is commonly used for both acute and maintenance therapy with the only formulation approved in the United States for bipolar disorder being extended-release carbamazepine, although other formulations can be used. Some data support the use of oxcarbazepine, a 10-keto analog of carbamazepine, in the treatment of bipolar disorder. However, it is not approved for the treatment of bipolar disorder in the United States. Valproate, carbamazepine, and oxcarbazepine all have a wide range of neurologic, GI, electrolyte, and hematologic adverse effects that require regular assessment and routine blood work.[43,45,46] Lamotrigine is FDA-approved for the maintenance treatment of bipolar I disorder. This medication is most effective in the prevention of relapse of depression.[2]

Valproate Sodium and Valproic Acid

Valproate has antimigraine, mood-stabilizing, and antiaggressive effects.[45] In 1995, the enteric-coated formulation divalproex sodium (sodium valproate) was approved for the acute treatment of mania. Data have shown valproate to be more effective than placebo for acute mania and perhaps as effective as lithium and olanzapine.[68] In addition, valproate can potentially be more effective than lithium in certain subtypes of bipolar disorder (eg, multiple prior episodes, mixed features, comorbid substance use disorder).[2] Valproate reduces or prevents recurrent manic, depressive, and mixed episodes.[2]

Giving lithium, carbamazepine, antipsychotics, or benzodiazepines with valproate can augment its antimanic effects. The addition of valproate to lithium can have synergistic effects in patients who are treatment-refractory and have specifiers of rapid cycling or mixed features, and the combination has demonstrated efficacy in maintenance therapy for bipolar I disorder. Combinations of valproate and carbamazepine can have synergistic effects, but the potential drug interactions make blood level monitoring of both agents essential.[2] Adding adjunctive SGAs to valproate can be effective for breakthrough mania if there is incomplete or partial response to monotherapy, or for quicker time to treatment response. Clozapine, olanzapine, and quetiapine can increase the risk of sedation and weight gain when combined with valproate. The combination of valproate and lamotrigine can be effective, but valproate reduces the clearance of lamotrigine leading to increased risk of serious rashes, ataxia, tremor, sedation, and fatigue.[45]

Adverse Effects

The most frequent dose-related adverse effects with valproate are GI complaints (eg, anorexia, nausea, indigestion, vomiting, mild diarrhea, and flatulence), fine hand tremors, and sedation.[45] The GI complaints are usually transient, but they can be minimized by giving the medication with food, using lower initial doses with gradual increases in doses, or switching to divalproex sodium extended-release tablets.[2] Dose reduction or the addition of a β-blocker can alleviate tremors, and giving the total daily dose at bedtime can minimize daytime sedation.[22]

Other adverse effects of valproate include ataxia, lethargy, alopecia, changes in the texture or color of hair, pruritus, prolonged bleeding because of inhibition of platelet aggregation, transient increases in liver enzymes, and hyperammonemia.[45] Increased appetite and propensity for significant weight gain is associated with long-term therapy, and should be considered prior to combining with agents that also cause weight gain (eg, SGAs). Thrombocytopenia can occur at higher doses, and patients should be monitored for bleeding and bruising. Lowering the valproate dose can restore platelet counts to normal levels.[22] Fatal necrotizing hepatitis is a rare idiosyncratic, non–dose-related adverse effect that has occurred in children with epilepsy receiving multiple antiseizure drugs.[45] A life-threatening hemorrhagic pancreatitis has been reported in both children and adults.[45] An in-depth discussion of adverse effects can be found in Chapter 75, "Epilepsy."

Drug-Drug Interactions

A summary of drug-drug interactions for valproate can be found in Chapter 75.

Dosing and Administration

For healthy inpatient adults with acute mania, the initial starting dosage of valproate is typically 20 mg/kg/day in divided doses over 12 hours.[45] The daily dose is adjusted by 250 to 500 mg every 1 to 3 days based on clinical response and tolerability. Maximum recommended dosing is 60 mg/kg/day (see Table 89-5).[45] For outpatients experiencing hypomania or euthymia, or for older patients, the initial starting dose is generally lower (5-10 mg/kg/day in divided doses) and gradually titrated to avoid adverse effects. Once an optimal dose has been achieved, the total daily dose can be continued in two divided doses or given once at bedtime if tolerated.[45] Extended-release divalproex can be administered once daily, but bioavailability can be 15% lower than that of immediate- and delayed-release products, thus requiring slightly higher doses.[45,69] In clinical practice, patients with bipolar disorder who are stable can be switched between formulations without having to change the dose. This is not the case for patients with seizure disorders.

Recommended baseline and routine laboratory tests for patients taking valproate are listed in Table 89-6. Although therapeutic serum concentrations of valproic acid have not been established in bipolar disorder, most clinicians use the antiseizure therapeutic serum range of 50 to 125 mcg/mL (mg/L; 347-866 μmol/L) taken 12 hours after the last dose.[2,45] Levels greater than 94.1 mcg/mL (mg/L; 652 μmol/L) have been found to have greater efficacy for bipolar mania.[70] Patients with cyclothymia or mild bipolar II disorder can have a therapeutic response to lower doses and blood levels, whereas some patients with a more severe form of bipolar disorder can require up to 150 mcg/mL (mg/L; 1,040 μmol/L). Serum valproic acid levels are most useful when assessing for adherence and toxicity.[2]

Carbamazepine

Carbamazepine, a iminostilbene derivative, is structurally related to tricyclic antidepressants (TCAs).[46] It is not a first-line agent for bipolar disorder and is generally reserved for use after treatment failure with lithium or divalproex sodium due to drug interactions and other safety concerns.[2] Data supporting the use of carbamazepine for bipolar depression are lacking and are not strong for the routine use of carbamazepine in maintenance treatment.[2] Patients with a history of head trauma, anxiety, or a substance use disorder may respond to treatment with carbamazepine. The combination of carbamazepine with lithium, valproate, and antipsychotics is often used for treatment-resistant patients experiencing a manic episode.[2]

Adverse Effects

A summary of adverse effects for carbamazepine can be found in Chapter 75. Acute overdoses are potentially lethal, and serum levels above 15 mcg/mL (mg/L; 63 μmol/L) are associated with ataxia, choreiform movements, diplopia, nystagmus, cardiac conduction changes, seizures, and coma.[22] Gastric decontamination, hemoperfusin, ECG monitoring, and symptomatic treatment are recommended for the management of carbamazepine toxicity.[22,71] New information is quickly evolving in the area of pharmacogenomics that may help clinicians individualize treatment for patients with bipolar disorder. Pharmacogenetic testing is available to determine if patients are poor or rapid metabolizers of cytochrome P450 2D6 and 2C19, as well as other important pharmacogenomic variants, thus predicting an individual's potential to respond to particular therapies as well as help to tailor dosing regimens in an effort to reduce adverse effects. The use of commercially available testing panels is controversial; however, the Clinical Pharmacogenomic Implementation Consortium (CPIC), funded by the National Institutes of Health, has resources to guide clinicians in the use of this information (http://cpicpgx.org/). For carbamazepine in particular, a boxed warning is located in the FDA package insert recommending genetic testing for the human leukocyte antigen (HLA) allele, HLA-B 1502, in patients of Asian ancestry to help detect a higher risk of Stevens–Johnson syndrome and toxic epidermal necrolysis.[46] Similar considerations should be made for patients prior to prescribing oxcarbazepine based on manufacturer's labeling.[43]

Drug-Drug Interactions

There are numerous drug-drug interactions that clinicians must consider when prescribing carbamazepine as it significantly induces the hepatic cytochrome P450 isoenzyme 3A4 and to a lesser degree 1A2, 2C9/10, and 2D6, which increases the metabolism of many medications (eg, quetiapine, lurasidone).[46] Individuals taking oral contraceptives who receive carbamazepine should be counseled to use alternatives such as intrauterine devices or depot medroxyprogesterone acetate in addition to barrier methods of birth control.[72]

Carbamazepine is metabolized to an active 10,11-epoxide metabolite; thus, medications that inhibit 3A4 isoenzymes can result in carbamazepine toxicity (eg, valproate, diltiazem, fluconazole, ketoconazole, nefazodone, verapamil).[46] Combining clozapine and carbamazepine is not recommended because of decreased clozapine concentrations and the possibility of bone marrow suppression with both agents.[46]

Dosing and Administration

During an acute manic episode in most hospitalized patients, carbamazepine can be started at 400 to 600 mg/day in divided doses with meals and increased by 200 mg/day every 2 to 4 days up to a usual range of 1200 to 1600 mg/day.[46] In outpatients, the initial dose of carbamazepine should be lower, and in all patients, the dose should be titrated gradually until response is achieved or there is evidence of toxicity. Conversely, some patients may require up to 1600 to 1800 mg/day.[46] Many patients are able to tolerate once-daily dosing of carbamazepine once their mood episode has stabilized. During the first month of therapy, serum concentrations of carbamazepine may be affected due to autoinduction of cytochrome P450 3A4 enzymes.[46]

Carbamazepine serum levels are usually obtained every 1 to 2 weeks during the first 2 months and then every 6 to 12 months during maintenance therapy.[2,46] Trough serum levels should be drawn 10 to 12 hours after the dose at least 2 to 5 days after a dosage change.[46] Although there is no correlation between carbamazepine serum concentration and degree of mania or depressive symptom response, most clinicians attempt to maintain levels between 6 and 10 mcg/mL (mg/L; 25 and 42 μmol/L). Although some treatment-resistant patients can require serum concentrations of 12 to 14 mcg/mL (mg/L; 51-59 μmol/L). Recommended baseline and routine laboratory tests for carbamazepine are listed in Table 89-6.

Oxcarbazepine

There are currently less data supporting the use of oxcarbazepine than carbamazepine in the treatment of bipolar disorder. Guidelines typically recommend oxcarbazepine as a third-line treatment option for bipolar mania, and it is not recommended for the treatment of bipolar depression.[2]

Adverse Effects

Severe and sometimes life-threatening dermatologic reactions (eg, Stevens–Johnson syndrome) have been reported; therefore, oxcarbazepine should be discontinued at the first sign of a skin reaction.[43] Risk of this adverse effect may be greater in patients with specific genetic markers similar to carbamazepine. Other adverse effects may include impaired cognitive or psychomotor performance, somnolence or fatigue, and coordination difficulties.[43] Incidence of hyponatremia with oxcarbazepine is greater than that seen with carbamazepine, ranging from 0.14% to 73.3% versus 4.8% to 31.3%, respectively, in clinical studies depending on study design and serum sodium cut offs.[74] An in-depth discussion of adverse effects can be found in Chapter 78, "Parkinson Disease."

Drug-Drug Interactions

Oxcarbazepine, a cytochrome P450 2C19 enzyme inhibitor and a 3A4/5 enzyme inducer, has the potential for causing drug interactions.[43] It induces the metabolism of oral contraceptives; thus, alternative contraceptive measures are required.[72] Additional drug interactions can be found in Chapter 78.

Dosing and Administration

Initial dosing usually follows that of epilepsy at 150 to 300 mg twice daily, with daily doses being increased by 300 to 600 mg every 3 to 6 days up to 1,200 mg/day in divided doses (with or without food).[43]

Lamotrigine

Lamotrigine is effective for the maintenance treatment of bipolar I disorder in adult patients.[2,22] Doses of 200 mg/day are more effective than lower doses, and there are no advantages to using 400 mg/day.[75] Lamotrigine has mood-stabilizing effects; it may have augmenting properties when combined with lithium or valproate and have low rates of switching patients to mania.[2] Although lamotrigine is not effective for acute mania when compared with standard mood stabilizers, it may be beneficial as maintenance therapy of treatment-resistant bipolar I and II disorders.[2] It is also effective for acute bipolar depression,[2,76] and it is most effective for the prevention of bipolar depression; therefore, clinically, it is often used in the treatment of patients with bipolar II. There are case reports of possible lamotrigine-induced mania when added to lithium, carbamazepine, and valproate.[77] In each of these cases, the patients had depressive mood symptoms or rapid mood changes requiring additional therapy.[77]

Adverse Effects

Common adverse effects include headache, nausea, dizziness, ataxia, diplopia, drowsiness, tremor, rash, and pruritus.[44] Approximately 10% of individuals treated with lamotrigine will develop a non-serious rash.[2] Although most rashes are self-limiting and resolve with continued treatment, some progress to life-threatening conditions such as Stevens–Johnson syndrome. The incidence of rash is greatest with co-administration of valproate, with higher than recommended initial doses, and with rapid dose escalation.[2,44] Patients should be warned about the rash and the need for discontinuing lamotrigine and seeking medical attention if the rash is diffuse, involves mucosal membranes, and is accompanied by a fever or sore throat. For an in-depth discussion of the adverse effects of lamotrigine, see Chapter 78.

Drug-Drug Interactions

Valproate decreases the clearance of lamotrigine (ie, more than doubles the half-life), and lamotrigine must be administered at a reduced dosage of approximately half the standard dose.[44] For an in-depth discussion of drug-drug interactions with lamotrigine, see Chapter 78.

Dosing and Administration

For the maintenance treatment of bipolar disorder, the usual dosage range of lamotrigine is 50 to 300 mg/day. The target dose is generally 200 mg/day (100 mg/day in combination with valproate and 400 mg/day in combination with carbamazepine).[44] For patients not taking medications that affect lamotrigine clearance, the dose is 25 mg/day for the first 2 weeks of therapy, 50 mg/day for weeks 3 and 4, 100 mg/day for week 5, and 200 mg/day for week 6 and beyond.[44] Patients who stop lamotrigine therapy for more than a few days should be restarted on a low dose and titrated every 2 weeks back to their maintenance dose.[44]

Antipsychotics

FGAs and SGAs such as aripiprazole, asenapine, haloperidol, olanzapine, quetiapine, risperidone, and ziprasidone are effective as monotherapy or adjunctive therapy in the treatment of acute mania.[2] Controlled studies in acute mania with lithium or valproate plus an antipsychotic suggest greater efficacy with combination therapies compared to these agents alone.[2,22] The FGAs (eg, chlorpromazine and haloperidol) are effective in acute mania, particularly those with psychosis and psychomotor agitation,[2,22] while the SGAs have demonstrated similar efficacy for the treatment of acute mania associated with agitation, aggression, and psychosis.[2]

Treating acute bipolar depression is challenging, and some antipsychotics may play a useful role. Multiple large randomized controlled trials support the use of quetiapine and lurasidone as a monotherapy and adjunctive treatment options for bipolar depression.[2] Data also support the use of combined fluoxetine/olanzapine in treating bipolar depression.[2]

Oral aripiprazole, olanzapine, sublingual asenapine, and long-acting risperidone are effective and FDA approved as monotherapy options for maintenance treatment in bipolar disorder.[2,47] Long-acting injectable FGAs (eg, haloperidol decanoate, fluphenazine decanoate) can have a place in maintenance treatment of bipolar disorder for patients who are non-adherent or treatment-resistant.[2] Clozapine adjunct and monotherapy has acute and long-term mood-stabilizing effects in refractory bipolar disorder but requires regular white blood cell monitoring for agranulocytosis.[2] The long-term safety of antipsychotics as monotherapy or as adjunctive therapy for bipolar maintenance treatment should be evaluated with ongoing assessment of utility.[2] Refer to Table 89-5 for antipsychotic specific indications. Metabolic syndrome is comorbid in 20-65% of patients with bipolar disorder; therefore, the risks versus benefits must be weighed due to the long-term metabolic and endocrine adverse effects (eg, weight gain, type 2 diabetes, hyperlipidemia, hyperprolactinemia) in addition to tardive dyskinesia that antipsychotics may cause.[2,78]

Adverse Effects

A summary of adverse effects for antipsychotics can be found in Chapter 87, "Schizophrenia."

Drug-Drug Interactions

A summary of drug interactions with antipsychotics can be found in Chapter 87.

Dosing and Administration

For acute mania, higher initial doses of antipsychotics may be required (eg, olanzapine 20 mg/day in hospitalized patients). Once the acute mania is controlled (usually within 7-28 days), the antipsychotic can be gradually tapered and discontinued, and the patient maintained on the mood stabilizer monotherapy as appropriate.

Monitoring

⑦ Recommendations for baseline and routine laboratory testing for patients receiving antipsychotics are found in Table 89-6.

Alternative Medication Treatments

⑧ Some patients can be stabilized on one mood stabilizer, but others may require combination therapies or adjunctive agents during an acute mood episode. If possible, adjunctive agents should be tapered and discontinued when the acute mood episode remits and the patient is stabilized.

Benzodiazepines

Benzodiazepines such as clonazepam and lorazepam may be used as an alternative to or in combination with antipsychotics when patients are experiencing acute mania, agitation, anxiety, panic, and insomnia, or cannot take mood stabilizers (eg, during the first trimester of pregnancy).[2] Risk versus benefit should be carefully weighed in patients with a history of substance use disorders and/or acute risk for suicide.[2] Lorazepam is available for intramuscular injection and is useful in the acute management of agitation. Benzodiazepines cause minimal adverse effects compared with antipsychotics, and at higher doses, rapidly sedate patients experiencing agitation. They can cause CNS depression, sedation, cognitive and motor impairment, dependence, and withdrawal reactions. When no longer required, benzodiazepines should be gradually tapered and discontinued to avoid withdrawal symptoms.

Antidepressants

For many years, antidepressants were recommended as adjunctive therapy for acute bipolar depression. Data from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) suggest that adjunctive antidepressants may be no better than placebo for acute bipolar depression when combined with mood stabilizers.[79] A meta-analysis of six trials identified a small treatment effect on clinician-rated depressive symptoms when antidepressants such as selective serotonin reuptake inhibitors (SSRIs) and bupropion were added to lithium, antiseizure drugs, or SGAs.[2,80] The concern of mood switching (ie, rapidly switching from depression to mania or hypomania) with the use of antidepressants is valid, although not common. Data show that the rate of mood switch with dual-acting agents (eg, TCAs or venlafaxine) is higher, and thus, these agents should be used with caution.[81] Additionally, the type of bipolar disorder may play a role in increased risk of mood switching, in that patients with bipolar I may carry a greater risk.[81] Controversy exists concerning the use of antidepressants, and many clinicians and treatment guidelines consider them to be second or third line in treating acute bipolar depression and should be avoided or used with extreme caution in patients with a history of antidepressant-induced mania/hypomania, mixed features, or recent rapid cycling.[2] Generally before initiating therapy with an antidepressant, it is important to ensure that the patient is on a therapeutic dosage or blood level of a primary mood stabilizer.[2] Patients who have a history of mania after a depressive episode should be treated cautiously with antidepressants.[22] For more information, see Chapter 88 for comparisons among antidepressants.

Special Populations

The approach for treating bipolar disorder in special populations can vary among clinicians. Patients with comorbid medical conditions or concomitant substance use, those older than 65 or younger than 18 years, and pregnant individuals can require different treatment approaches.

Bipolar Disorder in Pregnancy

Comprehensive management during pregnancy is important to decrease the risk of birth defects, perinatal complications and mortality, preterm birth, low birth weight, low Apgar scores, and adverse neurodevelopmental effects.[2,82] Pharmacotherapy during pregnancy is complicated, and the risk-to-benefit ratio must be weighed. Clinicians should always use the lowest effective dose of any medication during pregnancy. Monotherapy should also be considered in order to decrease the risk to the pregnant individual and child. Contraception and pre-conception counseling should be a part of the patient education plan for individuals of child-bearing age diagnosed with bipolar disorder, who are able to become pregnant.[2] Education should include information regarding the risk of medications for the fetus, the impact of pregnancy on bipolar illness and vice versa. Additionally, consideration into contraceptive methods should take into account that antiseizure drugs such as carbamazepine and lamotrigine may have pharmacokinetic interactions with oral contraceptives.[2]

When lithium is given during the first trimester, the prevalence of Ebstein's anomaly is estimated between 1 and 10:1000 and the risk of neural tube defects is 13:1000.[82] Though newer data may suggest that the absolute risk of cardiac abnormalities may be small, lithium use is generally not recommended in the first trimester of pregnancy unless the benefit outweighs the risk.[2,83,84] Lithium freely crosses the placenta and is found in equal concentrations in the fetal and pregnant person's blood.[42] When lithium is used during pregnancy, it should be tapered down to the lowest effective dose necessary to decrease the risk of relapse. Lithium can cause perinatal complications in the infant such as hypotonia, jaundice, cyanosis, and lethargy.[82] Dose adjustments and close monitoring of serum levels will be needed due to changes in glomerular filtration rates and renal perfusion rates during pregnancy and immediately after delivery.[57,82] Milk concentrations of lithium range from 30% to 50% of the adult's serum concentration, and serum concentrations in the nursing infant are 10% to 50% of the adult's; thus, nursing is usually discouraged.[42,57]

Neural tube defects cause the most concern for clinicians treating pregnant patients during their first trimester. Data from the North American Antiepileptic Drug Pregnancy Registry show the risk of neural tube defects is about 0.12% for non-exposed babies.[85] Carbamazepine's risk of neural tube defects is estimated to be 3%.[85] Carbamazepine is excreted in breast milk with a milk-to-plasma ratio of ~0.4.[46] Craniofacial abnormalities, developmental delays, microcephaly, and other abnormalities are also of concern when using antiseizure drugs. For pregnant patients treated with lamotrigine, the risk of neural tube defects is estimated to be 2%, but data for lamotrigine are limited compared with those for some older antiseizure drugs.[85] If the pregnant individual requires lamotrigine while nursing, infants should be monitored as infant concentrations can reflect 18 to 50% of the parent's serum concentration.[86,87] Valproate is usually not recommended during the first trimester of pregnancy because the risk of neural tube defects is estimated to be 4%.[85] Australian registry data in patients with epilepsy show dose-related teratogenicity with doses greater than 1,100 mg/day of valproate.[88] Additionally, data from the North American AED (Antiepileptic Drug) Pregnancy Registry showed that the median daily dose for first trimester exposure in babies born without malformations was 750 mg.[85] Fetal valproate syndrome is characterized by abnormalities such as facial clefts, cardiac and limb defects, and abnormal facial features.[86] Administration of folate can reduce the risk of neural tube defects; therefore, the risks versus benefits of using valproate during pregnancy must be discussed with the patient.[2] Individuals of childbearing age, able to become pregnant receiving valproic acid and those currently pregnant should receive folic acid supplementation; however, there is not a consensus on the recommended folic acid dose to use. Valproate is excreted into human milk in low concentrations and is considered to be compatible with nursing.[45] One case report of thrombocytopenia and anemia from valproate exposure has been reported in a nursing infant.[45] If the nursing parent receives valproate, the infant should have identical laboratory monitoring.

Caution should be used when prescribing antipsychotics during pregnancy. FGAs have been prescribed for many years in pregnancy and data show little teratogenic risk, but the data are not without question.[89] Data on the SGAs are limited, and clinicians should consider the potential risk of gestational diabetes.[89] Extrapyramidal symptoms, neonatal withdrawal, and sedation should also be considered when using both FGAs and SGAs during the third trimester of pregnancy.[89] There is still a paucity of human data with antipsychotics, and therefore, risk-to-benefit ratio must be weighed.

Child and Adolescent Bipolar Disorder

Approximately one-third to two-thirds of patients diagnosed with bipolar disorder experience their first episode as a child or adolescent; however, there are few controlled studies in this population.[2] Little is known about the long-term efficacy and safety of specific agents or combination therapies in this population.[90] Lithium is the only medication approved as a mood stabilizer for children and adolescents and its efficacy in pediatric manic or mixed states has been documented in one double-blind placebo-controlled trial as well as an open-label trial.[90] Age restrictions vary by formulation, with immediate-release lithium being approved in children age 7 years and older for acute manic or mixed episodes and maintenance treatment, and extended-release being approved in children aged 12 years and older for acute manic and mixed episodes.[42] Valproate and carbamazepine are utilized in pediatric patients based on experience in adults.[2,90]

Aripiprazole and risperidone are FDA-approved for bipolar mania or mixed states in patients aged 10 to 17 years.[90] Quetiapine and quetiapine XR are approved as monotherapy or adjunct to lithium or divalproex in patients aged 10 to 17 years during a manic or mixed episode, but it did not show efficacy in two double-blind, placebo-controlled studies in children and adolescents with bipolar depression.[2,90] Olanzapine is approved for use in patients with manic or mixed episodes aged 13 to 17 years as well as for monotherapy maintenance treatment in this subset of patients.[67] Ziprasidone has supporting data for its use in pediatric acute mania but does not have FDA approval.[6] Lurasidone's approval includes monotherapy treatment of bipolar depression in children 10 years of age and older.[91] Therefore, long-term data are still needed and recommendations on the treatment of pediatric bipolar depression and maintenance treatment are lacking due to insufficient data.[2] Additionally, children and adolescents treated with SGAs are more susceptible to metabolic effects of these medications, requiring close attention to diet and physical exercise.[2]

Bipolar Disorder Management in Individuals with Co-morbidities

Patients with bipolar illness are more likely to have medical comorbidities than the general population complicating the management of bipolar disorder in older adults who average three to four medical comorbidities (eg, hypertension, diabetes).[2] Older adults may be more susceptible to mood stabilizer and antipsychotic adverse effects. Anticholinergic burden of medications should be considered when prescribing.[2] Specific for lithium and aging, reductions in renal clearance may significantly increase the elimination half-life in older patients requiring more frequent renal monitoring.[42] The elimination of valproate has been reported to also decrease with age and has been associated with motor side effects and metabolic effects in older patients.[2,45] The efficacy and tolerability of lithium and divalproex sodium for acute manic, hypomanic, or mixed episodes in patients age 60 years and older have been compared in one randomized double-blind trial.[92] Both medications were efficacious at serum concentrations between 0.8 and 0.99 mEq/L (mmol/L) for lithium and 80 to 99 mcg/mL (mg/L; 555-686 μmol/L) for divalproex, though greater reduction in manic symptoms was seen with lithium at the expense of tremor.[92]

EVALUATION OF THERAPEUTIC OUTCOMES

The establishment and maintenance of a therapeutic alliance between the patient and clinician is essential in monitoring a patient's psychiatric status and safety; enhancing treatment adherence; promoting good nutrition, sleep, and exercise; identifying stressors; recognizing new mood episodes; and minimizing adverse reactions and drug interactions.[2] Patients who have a partial response or non-response to established bipolar therapies should be reassessed for an accurate diagnosis, concomitant medical or psychiatric conditions, adherence with treatment (including blood levels if appropriate), and medications or substances that exacerbate mood symptoms. Non-adherence to medication treatment, delusional symptoms, alcohol or substance use, rapid cycling, or mixed states are often associated with poorer treatment outcomes.

CONCLUSION

The diagnosis and treatment of bipolar disorder can be complicated. Once an accurate diagnosis is made, clinicians must collaborate with patients and follow the patient centered model to select the best treatment regimen. Clinicians must educate patients to be diligent in self-monitoring of their disease and the reporting of medications adverse effects. Adherence with medications is a key component in treatment. Clinicians must realize that there are various options for treating each phase of bipolar disorder and selection of the correct medication is essential to achieve optimal patient outcomes.

SELF-ASSESSMENT QUESTIONS

1. The preferred treatment option for a 20-year-old patient with bipolar disorder who has severe liver disease is:

A. Valproic acid

B. Lithium

C. Carbamazepine

D. Oxcarbazepine

2. During the lag time for onset of action of lithium, an appropriate adjunctive medication for acute mania might include a medication from which of the following classes?

A. Antihistamines

B. Benzodiazepines

C. Beta-blockers

D. Antidepressants

3. Lamotrigine should be used for which phase of bipolar disorder?

A. Acute mania

B. Acute depression

C. Maintenance

D. Rapid cycling

4. If lamotrigine is initiated in a patient receiving valproic acid (VPA), the starting dose of lamotrigine should be:

A. Lower than if started in a patient not receiving VPA

B. Higher than if started in a patient not receiving VPA

C. The same as in a patient not receiving VPA

D. Lamotrigine is contraindicated in patients receiving VPA

5. Which of the following laboratory tests is needed prior to initiating therapy with valproic acid?

A. Potassium level

B. Liver function test

C. Thyroid function test

D. Magnesium level

6. Which adverse effect is more frequently associated with oxcarbazepine than carbamazepine?

A. Ataxia

B. Nausea and vomiting

C. Stevens–Johnson syndrome

D. Hyponatremia

7. All of the following are symptoms of acute mania *except*:

A. Grandiosity

B. Racing thoughts

C. Decreased appetite

D. Pressured speech

8. Antidepressants may be considered when treating a patient with bipolar disorder who is currently:

A. Depressed, with a history of treatment-resistant depression

B. Not depressed, but has a history of severe depression before each manic episode

C. Hypomanic, but has a history of severe depression

D. Manic, but has a history of severe depression after a manic episode

9. A diagnosis of bipolar I disorder comes only after a patient has a:

A. Manic episode

B. Hypomanic episode

C. Depressed episode

D. Both A and B

10. Antipsychotics could be used in a patient displaying which of the following symptoms?

A. Mania with psychotic features

B. Mania without psychotic features

C. Depression with psychotic features

D. All of the above.

11. A first-line treatment option in a patient with bipolar disorder current episode manic is:

A. Lithium

B. Carbamazepine

C. Lamotrigine

D. Oxcarbazepine

12. Which of the following medication lists would be appropriate for a patient who is currently experiencing a manic episode?

A. Lamotrigine, lorazepam, olanzapine

B. Carbamazepine, fluoxetine, olanzapine

C. Haloperidol, lorazepam, fluoxetine

D. Valproic Acid, lorazepam, olanzapine

13. Which medication has an FDA indication for the treatment of bipolar depression?

A. Olanzapine

B. Quetiapine

C. Risperidone

D. Ziprasidone

14. Which medication has an FDA indication for maintenance therapy in bipolar disorder?

A. Olanzapine

B. Quetiapine

C. Risperidone

D. Ziprasidone

15. Which of the following laboratory tests is needed prior to initiating lithium therapy?

A. Potassium level

B. Platelet count

C. Thyroid function test

D. Magnesium level

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Lithium is cleared renally so this would be the best option for this patient. The other medications listed are all hepatically metabolized. See "Lithium" section and Table 89-6.

2. **B.** Benzodiazepines are effective in helping treat and resolve symptoms of mania. Antidepressants would potentially make mania worse. Beta-blockers and antihistamines are not used in treating mania. See "Alternative Medication Treatments" section.

3. **C.** Lamotrigine has the best data to support its use in the maintenance phase of the illness. It is not helpful in mania and does not have data to support its use in rapid cycling. There is controversial data for its use in acute depression. See "Antiseizure Medications" section.

4. **A.** It is recommended to decrease the dose of lamotrigine by 50% when used in combination with valproic acid. See "Lamotrigine" section and Table 89-5.

5. **B.** It is important to make sure patients being initiated on valproic acid have good liver function since this medication is cleared by the liver. Thyroid function is not needed, nor are magnesium or potassium levels. See "Valproate Sidium and Valproic Acid" section and Table 89-6.

6. **D.** Clinically significant hyponatremia and SIADH may develop during use with oxcarbazepine. See "Oxcarbazepine" section and Table 89-5.

7. **C.** A change in appetite is not a symptom of mania. See "Clinical Presentation and Diagnosis" section and Table 89-1.

8. **A.** Antidepressants should not be used in patients with a recent history of mania. If antidepressants are used they should only be used while the patient is depressed. When used without depression present it increases the risk of a switch to mania. See "Alternative Medication Treatments" section.

9. **A.** Mania and hypomania are what indicate bipolar disorder. See "Clinical Presentation and Diagnosis" section and Table 89-1.

10. **D.** Antipsychotics can be used to resolve mania with and without psychotic features. Antipsychotics are also used to treat the psychosis associated with severe depression. See "Antipsychotics" section.

11. **A.** Lithium is a first-line treatment option for mania. Carbamazepine and Oxcarbazepine are 3rd line options. Lamotrigine is not effective in treating mania. See "Pharmacologic Therapy" section and Table 89-4.

12. **D.** Valproic Acid, lorazepam, and olanzapine would be appropriate for treating mania. Lamotrigine is not effective. Fluoxetine should not be used as it could make the mania worse. See "Pharmacologic Therapy" section and Table 89-4.

13. **B.** Quetiapine is FDA-approved as monotherapy for the treatment of bipolar depression. See "Antipsychotics" section.

14. **A.** Olanzapine is approved by the FDA for monotherapy maintenance treatment. Risperidone Long Acting injection is also approved, but not oral therapy. See "Antipsychotics" Section.

15. **C.** Hypothyroidism can occur in patients taking lithium; therefore, it is important to have baseline values prior to initiation of therapy. See "Lithium" section and Table 89-6.

Chapter 91: Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder

Kristen N. Gardner; Jolene R. Bostwick; Ericka L. Crouse

KEY CONCEPTS

KEY CONCEPTS

1 Trauma-focused cognitive behavioral therapy (CBT) and eye movement desensitization and reprocessing are the most effective nonpharmacologic methods to reduce symptoms of posttraumatic stress disorder (PTSD).

2 The selective serotonin reuptake inhibitors (SSRIs) and venlafaxine at moderate to high dose are considered first-line treatments for PTSD.

3 An adequate trial of SSRIs in PTSD is 8 to 12 weeks.

4 Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.

5 CBT with behavioral techniques (eg, exposure and response prevention [ERP]) is the most common initial nonpharmacologic treatment of choice in obsessive-compulsive disorder (OCD).

6 Moderate-to-high dose SSRIs are the medication of choice for the treatment of OCD.

7 Clomipramine, a tricyclic antidepressant (TCA) with strong serotonin (5-HT) reuptake inhibition, is a second-line treatment option for OCD.

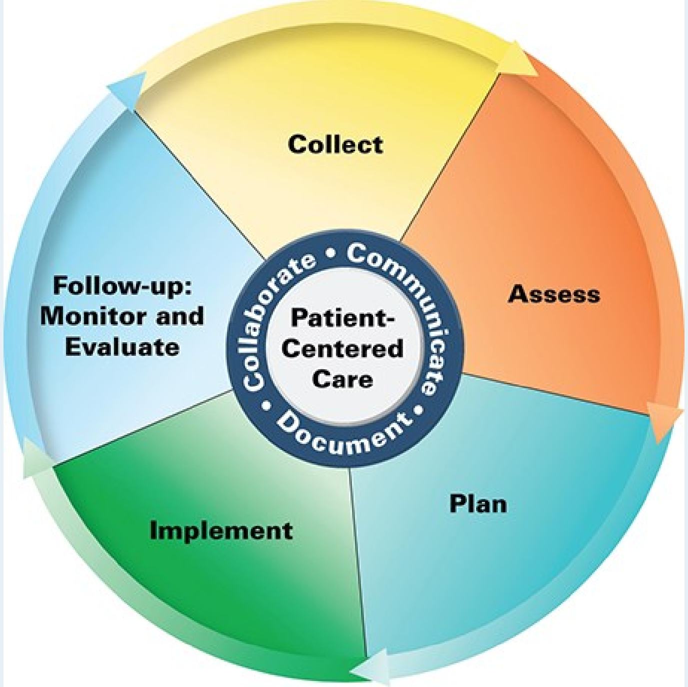
8 An adequate antidepressant trial for OCD treatment is 8 to 12 weeks.

9 Augmentation of SSRI treatment of OCD with low-to-moderate doses of antipsychotics may be helpful.

10 Medication taper can be considered after 1 to 2 years of treatment in patients with OCD.

PATIENT CARE PROCESS

Patient Care Process for Posttraumatic Stress Disorder and Obsessive-Compulsive Disorder



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history (personal and family, include first-degree relatives' response to medication)
- Social history (eg, tobacco use/ethanol use/substance use/sexual activity)
- Current medications including OTC use, herbal products, dietary supplements, and prior psychiatric medication use
- Patient health preferences, beliefs, and treatment goals
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight
    - Lipid panel and A1c or fasting blood sugar if starting antipsychotic therapy
    - Electrocardiogram (ECG) if starting a tricyclic antidepressant (TCA) in a patient with cardiovascular disease, patient <18 or >40 years of page, or with other risk factors for QT prolongation (eg, electrolyte abnormalities, concomitant medications with the potential to prolong the QT)
    - Validated rating scale score (eg, Clinician Administered PTSD Scale [CAPS] or Yale-Brown Obsessive-Compulsive Scale [Y-BOCS])
    - Results of any pharmacogenomics testing

Assess

- Target symptoms (eg, intrusion, avoidance, reactivity, mood/cognition for PTSD and obsessions and/or compulsions for OCD) using CAPS, Y-BOCS, or other rating scale assessments
- Functional impairment/quality of life
- Sleep hygiene

- Psychotic symptoms
- Engagement in psychotherapy
- Medication adherence
- Ability/willingness to utilize and pay for pharmacotherapy or engage in psychotherapy
- Ability/willingness to return to clinic for continued regular symptom assessment
- Need to alter treatment plans due to results of pharmacogenomics testing

Plan*

- Pharmacotherapy regimen including specific medication, dose, route, frequency, onset of action, and duration (see Fig. 91-1, Tables 91-1 through 91-4)
- Monitoring parameters including efficacy (eg, rating scale score, sleep, other symptoms such as irritability, functional impairment, symptom diary) and safety (eg, suicidal ideation, adverse effects including insomnia, worsening anxiety or depression, gastrointestinal distress, sexual dysfunction, agitation); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, lifestyle modification, onset of action, treatment duration, drug-specific information, medication administration technique; see Fig. 91-1 and Tables 91-2, 91-3, and 91-5)
- Self-monitoring for changes in PTSD/OCD symptoms, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, substance use treatment)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, CAPS/Y-BOCS or other rating scale assessments, adherence assessment, adverse effect assessment)
- Engage caregiver/family in treatment plan, if possible, and with patient permission

Follow-Up: Monitor and Evaluate

- Improvement in rating scale scores of PTSD/OCD symptoms
- Presence of medication related adverse effects (eg, sexual dysfunction, insomnia)
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate sleep hygiene
- Reevaluate effectiveness of psychotherapy
- Assess risk for suicidality

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

PTSD

Prior to class visit the website PTSD: National Center for PTSD on the US Department of Veterans Affairs website at: www.ptsd.va.gov. Expand the section "Understand PTSD" then "Types of Trauma" to review one or two types of trauma (eg, war and combat, violence and abuse, disaster and terrorism)

On the left-hand side menu, visit the section "For Providers" and complete the following steps:

1. Click on Assessment
2. Click on Adult Self-Report
3. Review the following screening tools: The PTSD Checklist for *DSM-5* (PCL-5)
4. Work with a friend or partner to role play and practice administering either the PCL-5

This activity is intended to build your awareness of different types of traumas that patients may experience as well as familiarize yourself with the types of symptoms that patients are screened for when considering a diagnosis of PTSD.

OCD

Identify a mobile-app that may help manage OCD and related symptoms (eg, nOCD, GGOC, Headspace). Evaluate the mobile-app from the perspective of a patient with OCD and write a brief review for this application (eg, a single paragraph). Consider the following questions (you do not need to address each item):

- What symptom(s) is this mobile-app intended to help?
- How interactive is the mobile-app in giving feedback to the end user?
- Can the mobile-app be personalized for the end user?
- Do you foresee the mobile-app content and delivery methods accomplishing its purpose?
- Is there scientific research that demonstrates its effectiveness?
- Describe the patient population for which this mobile-app is best suited.

This activity is intended to build your awareness of the growing interest and use of mobile health technology devices to empower patients in self-management of their mental health.

INTRODUCTION

Traumatic or stressful events (eg, wars, terrorist attacks, natural disasters, pandemics, robbery, physical or sexual assault) can lead to development of posttraumatic stress disorder (PTSD).[1] Initially diagnosed in veterans of war, PTSD is now acknowledged as a significant psychiatric illness in the civilian population and among deployed service personnel of the Afghanistan and Iraq campaigns in whom the suicide rate has escalated.[1,2] In clinical practice, PTSD continues to be poorly recognized and diagnosed.[3] Because of its co-occurrence (greater than 50%) with anxiety disorders, depression, substance use, and traumatic brain injury, the overlapping symptoms can lead to diagnostic uncertainty.[3] PTSD has been shown to increase the risk of lifetime suicide attempt.[3–7] Advances in the science and treatment of PTSD can assist clinicians in all fields to screen for a history of trauma and effectively manage PTSD.

Intrusive obsessive thoughts and compulsive ritualistic behaviors characterize obsessive-compulsive disorder (OCD),[1] with symptoms potentially being severe enough that they impair functioning in social, family, and work settings, and decrease overall quality of life (QOL). Comorbid depression is common with OCD, with approximately 40% of patients having a history of major depression during their lifetime.[6] A diagnosis of OCD is also associated with an increased risk of suicide, with a mean of 13.4% (range 1%-46.3%) of patients reporting a previous history of suicide attempt. Increased understanding of symptom dimensions and treatment response can improve QOL in patients suffering from OCD.

EPIDEMIOLOGY

Within the US population, the estimated lifetime prevalence of PTSD is 8.7%,[1] whereas the lifetime prevalence of OCD has been estimated at 2.3%.[8]

PTSD is associated with the incidence of trauma,[1] with the most frequently reported traumatic events in the US being assault (physical and sexual) with a 52% lifetime prevalence and accidents or fires with a 50% lifetime prevalence.[3] The conditional probability of developing PTSD differs between sex and type of trauma. The probability of developing PTSD for males and females after rape is 65% and 46%, after physical assault 2% and 22%, and after an accident are 6% and 9%, respectively.[7,9] Prevalence of PTSD is consistently higher among females (10.4%-12.3%) than males (5%).[7] Gender roles, genetic predispositions as well as hormonal influences may put females at higher risk of PTSD.[10] While the age of onset and course of PTSD are variable, it is important to note that PTSD can occur at any age, but most cases occur before the age of 40 years. The presentation is also not predictable, because symptoms are impacted by the duration and intensity of the trauma, the presence of other psychiatric disorders, and early post-trauma interventions.[3] Genetic factors can increase vulnerability to PTSD if an individual is exposed to a traumatic event. Lastly, veterans and those whose jobs increase the risk of traumatic exposure (eg, firefighters, first responders, police) have higher rates of PTSD.[1,3]

The epidemiology of OCD is also influenced by age and sex. The age of onset has a bimodal distribution peaking in late childhood/early adolescence and then again in early adulthood.[11,12] In males, the onset of illness is more frequently seen during childhood/adolescence versus early adulthood in females. The annual US prevalence of OCD is greater in females (1.8%) versus males (0.5%).[7] Patients with childhood-onset OCD often have concurrent ADHD and tic disorders whereas mood disorders, other anxiety disorders, and obsessive-compulsive personality disorder are common comorbidities in adult-onset OCD.[1] Greater than 50% of patients with Tourette Syndrome have OCD symptoms, and around 30% will eventually be diagnosed with OCD.[13] Patients with eating disorders have a wide range of reported comorbid OCD.[14] Heredity is stronger when there is an early age of onset or comorbidity with tic disorder.[1] The average delay in time to appropriate treatment for OCD following symptom onset is nearly 8 to 10 years[12] as OCD is a disorder that is poorly recognized and patients often do not seek treatment until late during illness.

ETIOLOGY

The exact etiologies of PTSD and OCD are unknown; however, it is likely that abnormalities in several areas of brain functioning interact to cause these chronic disorders. Genetics may play a role in PTSD and OCD expression, but environmental factors are also involved. A number of genetic markers for PTSD are under evaluation, including genes associated with the hypothalamic-pituitary-adrenal (HPA) axis (eg, FKBP5), the amygdala-medial prefrontal cortex (mPFC)-hippocampus circuit, and the serotonin transporter.[15-18] Given the heterogeneity and individual differences in course and presentation of PTSD, recent studies have focused on gene by environment (G x E).[16,18] There is increasing evidence of immune dysregulation in PTSD, but it is unknown if it is a predisposing factor versus comorbidity related.[18] The behaviors in OCD are also heterogeneous, suggesting OCD is a polygenic disorder.[13,19-21] Potential genes include those affecting serotonin (5-HT), dopamine (DA), and glutamate.[13] An association with the D_2 receptor gene has been identified in OCD with tics and other potential genes associated with OCD include 5-HT transporter and receptors (eg, 5-HT_{1D} beta, 5-HT_{2A}, and 5-HT_{2C}). Research on the role of glutamate in OCD has identified genes of interest including glutamate-related synapse (*SAPAP/DLGAP*); glutamate transporter (*SLC1A1*); and N-methyl-D-aspartate (NMDA) receptor genes (*GRIN2B* and *GRIK*).[13,19,20] Twin studies found higher concordance rates in monozygotic versus dizygotic twins, suggesting an approximate 48% OCD heritability. Some subtypes, such as early-onset OCD with tics, may have higher heritability.[20,21] Further understanding of the roles genetics and the environment play in the development of PTSD and OCD may impact future treatment strategies and are current research areas.

In children, the occurrence of sudden onset OCD and chronic tic disorder following a streptococcal infection has been reported and previously labeled

Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections (PANDAS).[20,21] Controversy currently exists as to whether PANDAS should be characterized as a subtype of OCD. Although most patients with OCD do not have a streptococcal etiology, an accurate medical history regarding onset of illness is imperative because specific treatment strategies are indicated. More recently, PANDAS has been broadened to pediatric acute-onset neuropsychiatric syndrome, or PANS, to include OCD symptoms that start after nonstreptococcal infections.

Substance/medication-induced OCD has been described with stimulants including cocaine, amphetamines, and methylphenidate. Furthermore, cases of OCD-like behaviors (eg, pathologic gambling) have been described with dopamine agonists (eg, ropinirole, pramipexole).[13]

PATHOPHYSIOLOGY

Research findings in the areas of neuroendocrinology, neurobiology, and neuroimaging have advanced theories on the pathophysiology of OCD, and PTSD. Neuroendocrine changes in the HPA axis are implicated in the pathophysiology of PTSD. The neurobiology of PTSD focuses on alterations in fear learning, threat detection, executive function, and emotional regulation, as well as contextual processing.[3] Dysfunction in the cortico-striato-thalamo-cortical (CSTC) circuit is implicated in OCD.[20,21] As reviewed in Chapter 90, "Generalized Anxiety Disorder, Panic, and Social Anxiety Disorders," data from neurochemical and neuroimaging studies indicate that the modulation of normal and pathologic anxiety states is associated with multiple regions of the brain (eg, amygdala, hippocampus, thalamus, and prefrontal cortex).[3] Abnormal function in several neurotransmitter systems, including norepinephrine (NE), γ-aminobutyric acid (GABA), glutamate, DA, and 5-HT, may affect the manifestations of OCD and PTSD.[16,22,23]

Neuroendocrine Theories

Neuroendocrine studies provide data that abnormalities occurring pretrauma, during trauma, and posttrauma contribute to PTSD. Trauma exposure is linked to abnormal HPA activity and cortisol patterns.[24] Normally the immediate reaction to stress occurs as an automatic response from the amygdala to the sympathetic and parasympathetic systems and the HPA axis.[22] The release of corticotropin-releasing factor (CRF) stimulates cortisol secretion from the adrenal gland and both catecholamines and cortisol levels rise in tandem. Cortisol then reduces the stress response by tempering the sympathetic reaction through negative feedback on the pituitary and hypothalamus[22] with both systems returning to normal after a few hours.

Data implicate a role for the neuropeptides CRF and neuropeptide Y (NPY) in PTSD, as patients with PTSD have a hypersecretion of CRF but demonstrate subnormal levels of cortisol at the time of trauma and then chronically.[22] Lower plasma cortisol concentrations were associated with greater severity of PTSD symptoms in nonmilitary patients[23] and dysregulation of the HPA axis is postulated to be a risk factor for eventual development of PTSD.[22] The NPY system is a mediator between exposure to stress and development of resilient versus maladaptive responses and the role of NPY in improving resilience is a continued area of research interest.[25]

Neurochemical Theories

Several neurotransmitters may be involved in the pathophysiology of PTSD as 5-HT, NE, and glutamate are associated with the processing of emotional and somatic contents of memories in the amygdala.[23] Alterations in these neurotransmitters are linked to alterations in amygdala activity.[3] The amygdala is involved in processing emotions, and acquiring, expressing, and regulating fear and traumatic memories, including fear conditioning.[24] The medial prefrontal cortex (mPFC) and hippocampus are involved in contextual processing. The noradrenergic theory posits that the autonomic nervous system of patients with anxiety is hypersensitive and overreacts to stimuli. The alarm center, the locus ceruleus, releases NE to stimulate the sympathetic and parasympathetic nervous systems. Hyperactive noradrenergic signaling in patients with PTSD is a consistent research finding and includes increased 24-hour catecholamine excretion.[23] Glutamate signaling abnormalities may result in distortion of amygdala-dependent emotional processing under stress.[22,23] Dysregulation of the processing of sensory input and memories may contribute to the dissociative and hypervigilant symptoms in PTSD. Abnormalities of GABA inhibition may lead to increased awareness or response to stress, as seen in PTSD.[26]

Both 5-HT and DA are implicated in the pathogenesis of OCD. Selective and potent serotonin reuptake inhibitors have consistently been shown effective for symptoms of the illness,[27] especially at higher doses. The most commonly studied serotonin receptors in OCD are 5-HT_{2A}, 5-HT_{1B}, and 5-HT_{2C}.[28] Dopamine dysregulation may also contribute to some forms of OCD, as neurologic symptoms (eg, tics) are part of the clinical presentation in some patients with OCD and Tourette Syndrome, a disorder of DA function.[1,13] Additionally use of dopamine agonists can worsen OCD symptoms, whereas augmentation with antipsychotic drugs may improve symptoms in patients with OCD who are partially responsive to selective serotonin reuptake inhibitors (SSRIs).[13] More recently glutamate has become another neurotransmitter of interest in OCD, especially in genetic research.[19]

Neuroimaging Studies

Neuroimaging studies suggest that certain areas of the brain are altered by psychological trauma. In PTSD, most functional neuroimaging studies have involved the amygdala, mPFC, dorsal anterior cingulate cortex (dACC), insula, and hippocampus.[3] Findings of increased activation of the amygdala after trauma-related imagery, sounds, or smells indicate that this structure plays a role in the persistence of traumatic memory.[29] Decreased amygdala activation is correlated with resilience to PTSD and response to CBT. Historically, studies have suggested patients with PTSD have reduced amygdala volume; however, a recent study suggested instead that smaller amygdala volume is related to exposure to trauma and not necessarily PTSD.[24] Hypofunctioning of the mPFC is theorized to prevent extinction of fear in patients with PTSD, and is associated with impairments in extinction recall, abnormalities in processing contextual information, and impairments in safety-signal learning.[3] Hyperresponsivity of the dACC, amygdala, and the insula may correlate with impaired response to emotional or salient stimuli or impaired threat detection. Not all magnetic resonance imaging (MRI) studies show reduced hippocampal volume in PTSD; however, reduced hippocampal volume has been linked to reexperiencing symptoms in PTSD.[24] In twin studies, the unaffected twin of patients with PTSD also demonstrated smaller hippocampi compared with twins without PTSD that may suggest that lower hippocampal volumes are likely a precursor associated with vulnerability for subsequent PTSD development.[22]

Neuroimaging studies consistently show evidence that dysfunction in the CSTC circuit, which regulates self-control, is associated with OCD.[13,19-21] The role of neuromodulation treatment in OCD supports the CSTC model.[21] Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) studies in OCD have shown increased activity in the anterior cingulate cortices, and different patterns of activation in the caudate.[11] Evidence suggests that lower pretreatment activity in the orbitofrontal cortex predicts a better response to SSRIs and improved fluvoxamine response has been correlated with abnormalities in the posterior cingulate cortex.

CLINICAL PRESENTATION

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) made several changes to the classification of anxiety and related disorders[1] with individual chapters for anxiety disorders, trauma- and stressor-related disorders, and obsessive-compulsive and related disorders. Generalized anxiety disorder, panic disorder, and social anxiety disorder are discussed in Chapter 90.

Posttraumatic Stress Disorder

Exposure to a traumatic event is required for a diagnosis of PTSD[1] in that the person must have witnessed, experienced, or been confronted with a situation that involved definite or threatened death or serious injury, sexual violence, or possible harm to self or others. Some examples of traumatic events include physical attacks by an intimate partner, severe traffic accidents, military combat, natural disasters, being held hostage, child sexual abuse, witnessing a murder or injury of another, and learning of a traumatic event that happened to a close family member or friend. While systematic reviews have yet to be conducted, the impact of the coronavirus (COVID-19) pandemic on PTSD has been published across populations, including healthcare workers experiencing PTSD and young adults with worsening PTSD symptoms.[30,31]

The resulting PTSD symptoms include persistent reexperiencing of the traumatic event, avoidance of stimuli associated with the trauma, numbing of general responsiveness, and persistent symptoms of hyperarousal.[1] Patients must have at least one intrusion symptom, at least one symptom of avoidance of stimuli associated with the trauma, at least two symptoms of negative alterations in cognition and mood, and at least two symptoms of increased arousal. Symptoms from each category need to be present for longer than 1 month and cause significant distress or impairment in functioning. Most persons diagnosed with PTSD also meet criteria for another psychiatric disorder, most commonly mood, anxiety, and substance use disorders.[1,4,32]

Anxiety and dissociative symptoms (eg, absence of emotional responsiveness, derealization, inability to recall important features of the trauma) emerging within 1 month after exposure to a traumatic stressor are classified as Acute Stress Disorder (ASD).[1] Symptoms of ASD are experienced during or immediately after the trauma, last for at least 3 days, and resolve within 1 month. The severity and course of illness is fluctuating and often worsens, with life stressors.

CLINICAL PRESENTATION: Posttraumatic Stress Disorder

Intrusion Symptoms

- Recurrent, intrusive distressing memories of the trauma
- Recurrent, disturbing dreams of the event
- Feeling that the traumatic event is recurring (eg, dissociative flashbacks)
- Physiologic reaction to or psychological distress from reminders of the trauma

Avoidance Symptoms

- Avoidance of conversations, thoughts, or feelings about the trauma
- Avoidance of people, places, or activities that are reminders of the event

Persistent Negative Alterations in Thinking and Mood

- Inability to recall an important aspect of the trauma
- Estrangement from others
- Restricted affect
- Negative beliefs about oneself
- Distorted beliefs causing one to blame others or themselves for the trauma
- Negative mood state

Hyperarousal Symptoms

- Decreased concentration
- Easily startled
- Self-destructive behavior
- Hypervigilance
- Insomnia
- Irritability or anger outbursts

Specifiers

- Dissociative symptoms: depersonalization or derealization
- With delayed expression: full criteria are not met until at least 6 months posttrauma

Data from References 1,32.

Obsessive-Compulsive Disorder

The diagnostic criteria for OCD require the presence of obsessions and/or compulsions that are severe enough to cause marked distress, to be time-consuming (occupy more than 1 hr/day), or cause significant impairment in social or occupational functioning.[1] An obsession is a recurrent, persistent idea, thought, impulse, or image that is experienced as intrusive and inappropriate and produces marked anxiety. A compulsion is defined as a repetitive behavior or act generally performed in response to an obsession. While it is most common for patients to have both obsessions and compulsions, some may only have one or the other. Diagnostically, the compulsive behavior is not pleasurable and is designed to prevent discomfort or the occurrence of a dreaded event that is often unknown and part of the obsession. Therefore, compulsive behaviors are usually performed according to certain rules or in a stereotyped fashion. Common symptom dimensions involve cleaning (eg, contamination obsessions and cleaning compulsions), symmetry (eg, symmetry obsessions and ordering or arranging compulsions), forbidden or taboo thoughts (eg, violent, sexual, or religious obsessions and related compulsions), and harm (eg, fears of causing harm or superstitions and related compulsions).[1,12] For example, patients obsessed with the fear of causing harm (eg, inadvertently hitting a pedestrian), may cause them marked distress and lead to repetitive checking (eg, driving past crosswalks to check for injured pedestrians).[12]

There are two specifiers for OCD related to the degree of insight and the presence of tic-related symptoms.[1] While individuals vary widely in their insight into the irrationality of their obsessive-compulsive symptoms, most will have good or fair insight. The addition of an insight specifier allows the diagnosis to include individuals with poor to absent insight such as those with comorbid psychosis.[12] Individuals with tic-related OCD appear to differ from those with non-tic-related OCD in terms of etiology, illness course, symptom presentation, comorbidities, heredity, and pharmacotherapy response.[1]

CLINICAL PRESENTATION: Obsessive-Compulsive Disorder

Obsessions

- Repetitive thoughts (eg, feeling contaminated by germs, fears of harming others)
- Repetitive images (eg, recurrent sexually explicit pictures)
- Repetitive urges (eg, need for symmetry or putting things in specific order)

Compulsions

- Repetitive activities (eg, hand washing, need to ask, need to confess)
- Repetitive mental acts (eg, counting excessively, repeating words silently, praying)

Specifiers

- Insight: good or fair insight, poor insight, or absent insight/delusional beliefs
- Related to a tic disorder

Data from References 1,12.

The diversity of OCD symptoms can obscure an accurate diagnosis as patients often present in a seemingly incongruous manner to non-mental health clinicians for other complaints—dermatologists for eczema or chapped skin, pediatricians for parental concerns over a child's compulsive hand washing, neurologists for tics, or dentists for gum lesions from compulsive teeth brushing.[12] Because patients recognize their compulsive behavior as illogical or irrational, they also can become extremely adept at denying symptoms, disguising their rituals, and concealing their illness from friends and family.[1]

It is important to note that OCD is a chronic illness in most patients, with symptom severity varying in intensity over time,[12] resulting in a significantly impaired QOL.

TREATMENT—POSTTRAUMATIC STRESS DISORDER

Desired Outcomes

The short-term goal of therapy in the management of PTSD is a reduction in core symptoms (eg, intrusive reexperiencing, avoidance, and hyperarousal). Additional goals include improvement in disability, concurrent psychiatric conditions, resilience, and QOL with the long-term goal of PTSD remission.

General Approach to Treatment

In general, individuals who seek treatment acutely after a trauma and are in intense distress should receive therapy based on their presenting symptoms (eg, a nonbenzodiazepine hypnotic for difficulty sleeping). Short courses of exposure-based, trauma-focused cognitive behavioral therapy (TFCBT) can be helpful to prevent chronic PTSD in patients with ASD or acute PTSD.[4] If symptoms (eg, hyperarousal, avoidance, dissociation, sleep difficulties, or depressed mood) persist for 3 to 4 weeks and the patient experiences marked social, occupational, and/or interpersonal impairment, they can be treated with pharmacotherapy, psychotherapy, or both. Many patients with PTSD will improve substantially with pharmacotherapy but retain some symptoms. Treatment regimens usually combine psychoeducation, psychosocial support and/or treatment, and pharmacotherapy; however, newer guidelines specifically emphasize the utility of individual trauma-focused psychotherapies.[3,5,33,34]

Nonpharmacologic Therapy

Psychotherapy can be used when a patient suffers from mild symptoms, in patients who prefer not to use medications, or in conjunction with medication in patients with severe symptoms to improve response.[5,35] Notably, current clinical practice guidelines emphasize the role of trauma-focused psychotherapy as the preferred treatment approach.[5,33,34] Patients who have experienced trauma should be educated that they can experience anxiety, depression, nightmares, and even flashbacks as a reaction to the event. Brief courses of individual trauma-focused psychotherapy, focusing on exposure or cognitive restructuring, near the traumatic event resulted in lower rates of PTSD 3 and 6 months later. Single-session critical incident stress debriefing has not shown to be effective in preventing development of PTSD and may cause harm.[3,5] Involving the patient in the selection of preferred treatment, especially in those that prefer prolonged exposure therapy, has demonstrated improved health-related QOL.[36]

① Psychotherapies for treating PTSD include prolonged exposure, TFCBT, cognitive processing therapy (CPT), eye movement desensitization and reprocessing (EMDR), and psychoeducation.[4,5,35] The unique treatment EMDR involves the process of patients imagining exposure to the traumatic event, while simultaneously engaging in bilateral eye movements to assist with processing of this event, along with relaxation.[4] The cognitive and behavioral approaches of TFCBT and EMDR are more effective than stress management or group therapy to reduce symptoms of PTSD. Psychoeducation includes information about the disease state, treatment options, and avoidance of excessive use of alcohol and other used substances. Evidence suggests insomnia associated with PTSD benefits from CBT.[5] Novel nonpharmacologic approaches (eg, interpersonal psychotherapy, narrative exposure therapy, written narrative exposure, imagery, transcranial magnetic stimulation [TMS], neurofeedback, acupuncture, yoga, emotional freedom technique, virtual reality exposure, somatic experiencing, mindfulness therapies, and delivery methods [eg, telemedicine and other technology-based treatments]) are under study.[3,5,37]

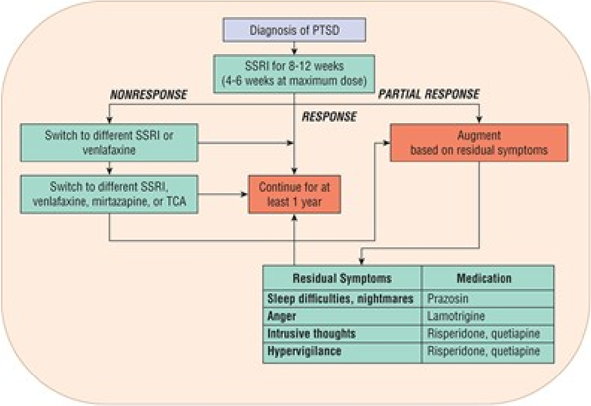
Pharmacologic Therapy

② Antidepressants are the major pharmacotherapeutic treatment for PTSD, in addition to also being effective for concurrent depression and anxiety disorders. SSRIs and venlafaxine are the first-line pharmacotherapy of PTSD[4–6,32,33,38,39,42,57]; however, the tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) can also be effective despite their less favorable side-effect profiles (Table 91-1). Both sertraline and paroxetine are approved for the acute treatment of PTSD,[40,41] and sertraline is approved for the long-term (eg, 52 weeks) management of PTSD.[41] A number of medications can be used as augmentation (eg, antiadrenergic agents, second-generation antipsychotics, and antiseizure medications).[4,5,42]

Benzodiazepines are not effective for PTSD.[5,32-34,39] A number of treatment guidelines are published,[4,5,32-34,42] with Table 91-2 providing a summary of key points from the treatment guidelines for PTSD. An algorithm for the treatment of PTSD appears in Fig. 91-1.

FIGURE 91-1

Algorithm for the pharmacotherapy of posttraumatic stress disorder (PTSD). (SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.) *(Data from References 38,39.)*



Diagnosis of PTSD
SSRI for 8-12 weeks (4-6 weeks at maximum dose)
NONRESPONSE
PARTIAL RESPONSE
RESPONSE
Switch to different SSRI or venlafaxine
Augment based on residual symptoms
Switch to different SSRI, venlafaxine, mirtazapine, or TCA
Continue for at least 1 year

Residual Symptoms	Medication
Sleep difficulties, nightmares	Prazosin
Anger	Lamotrigine
Intrusive thoughts	Risperidone, quetiapine
Hypervigilance	Risperidone, quetiapine

TABLE 91-1

Dosing of Antidepressants in the Treatment of PTSD

Drug	Brand Name	Initial Dose	Usual Range (mg/day)	Comments
SSRIs				
Fluoxetine	Prozac	10 mg daily	10-80[a]	
Paroxetine	Paxil, Pexeva	10-20 mg daily	20-50	Maximum dose is 60 mg daily[a]
Sertraline	Zoloft®	25 mg daily	50-100	Maximum dose is 200 mg daily[b]
Other Agents				
Amitriptyline	Elavil	25 or 50 mg daily	75-200[a]	
Imipramine	Tofranil	25 or 50 mg daily	75-200[a]	
Mirtazapine	Remeron	15 mg every night	30-60[a]	
Nefazodone	n/a	25-100 mg twice daily	150-600[a]	Product has a black box warning for hepatotoxicity
Phenelzine	Nardil	15 or 30 mg every night	45-90[a]	
Venlafaxine extended-release	Effexor XR	37.5 mg daily	75-225[a]	

[a] Dosage used in clinical trials but not FDA-approved.

[b] Dosage is FDA-approved.

PTSD, posttraumatic stress disorder; SSRIs, selective serotonin reuptake inhibitors; n/a, not applicable.

Data from References 5,32,30,41.

TABLE 91-2

Summary of Key Points in Treatment Guidelines for PTSD

Recommendations	Comments
First-Line Treatments	
- SSRIs: Fluoxetine, paroxetine, sertraline - SNRIs: Venlafaxine	At 4 weeks if there is partial response, continue for another 4 weeks. At 8 weeks, if no improvement, increase dose to maximum tolerated or switch to another first-line treatment
Second-Line Treatments	
TCAs: Amitriptyline, imipramine	The risk of adverse effects and potential for fatalities in a TCA overdose are higher than with SSRIs or SNRIs
Mirtazapine	
Augmentation with prazosin for sleep/nightmares	Not recommended in the VA guidelines ***for use in veteran population***
Third-Line treatments	
Augmentation with antiseizure medications or second-generation antipsychotics	The VA guidelines recommend against using risperidone as an augmenting agent secondary to metabolic adverse effects. There is insufficient evidence to support routine use of other second-generation antipsychotics or antiseizure medications
MAOIs: Phenelzine	Potential adverse effects and dietary restrictions limit use
Nefazodone	Risk for hepatotoxicity limits use

PTSD, posttraumatic stress disorder; SNRIs, serotonin–norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCA, tricyclic antidepressant; VA, Veterans Affairs.

Data from References 4,5,39.

Selective Serotonin Reuptake Inhibitors

The SSRIs pharmacologically enhance serotonergic functioning and large prospective guidelines document the efficacy and consistently recommend use of fluoxetine, sertraline, and paroxetine in the acute management of PTSD.[5,32-34,36,39] While a meta-analysis found that SSRIs were significantly better than placebo for the treatment of PTSD, the overall effect size was small.[43] Adverse reactions reported in patients with PTSD treated with SSRIs include gastrointestinal symptoms, sexual dysfunction, insomnia, and agitation. Additionally, long-term use of SSRIs (durations of 9-12 months) has been shown to be effective in preventing relapse.[4,42]

Other Antidepressants

The serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine has shown efficacy in PTSD. In a 12-week, placebo-controlled trial comparing venlafaxine extended-release and sertraline, venlafaxine was effective in reducing the avoidance/numbing and hyperarousal clusters of PTSD, whereas sertraline improved all PTSD symptom clusters.[44] The remission rates for venlafaxine extended-release were 30.2% after 12 weeks[44] and 50.1% after 6 months.[45] In one retrospective study, when compared with fluoxetine, sertraline, paroxetine, and topiramate, venlafaxine demonstrated higher 12-week acute phase remission rates, though additional studies are needed.[46]

Other antidepressants have been studied in controlled trials with mirtazapine considered a second-line agent in one guideline,[4] while others highlight insufficient data to recommend use.[5,32,37,42] Specifically, one recent prospective, placebo-controlled trial found mirtazapine did not reduce PTSD, depression, or insomnia symptoms among male combat veterans.[47] The TCAs amitriptyline and imipramine are considered second-line agents whereas phenelzine and nefazodone are considered third-line antidepressants if therapeutic trials of SSRIs or venlafaxine have failed. Potential adverse effects or risks associated with these agents (eg, daytime drowsiness and toxicity in overdose with TCAs; dietary restrictions and potential drug interactions with MAOIs; or risk of liver failure with nefazodone) limit their use clinically.[4,5,35,42] Bupropion is not recommended in patients with PTSD due to poor quality of evidence, but this agent may be considered as a third-line option.[4,5,32]

Alternative Medication Treatments

Second-generation antipsychotics, α_1-adrenergic receptor antagonists, and antiseizure medications can be used as augmenting agents for persistent PTSD symptoms, in cases of partial response to SSRI therapy after 4 to 6 weeks, or for comorbidities.[4,32,39,42,48] Data on the efficacy of second-generation antipsychotics are conflicting with one study showing quetiapine monotherapy was generally well tolerated and associated with improvements in overall symptomology, reexperiencing, and hyperarousal.[49] Further, guidelines suggest second-generation antipsychotics may be useful in targeting intrusive symptoms[4]; whereas others advise against use due to insufficient evidence[5,32] or use with caution.[33] Any potential benefit must be considered in the context of risks, including metabolic complications. One meta-analysis supports risperidone use among the second generation antipsychotics,[50] while other recent guidelines advise against use of any second-generation antipsychotic for PTSD due to limited evidence and adverse effect profile.[5,32]

Prazosin (an α1-adrenergic receptor antagonist) can be useful in some patients with PTSD, with earlier studies showing that it may decrease nightmares and symptoms of hyperarousal, increase total sleep time and sleep quality, and improve core PTSD symptoms. When used for PTSD the daily doses start at 1 mg and may be increased as tolerated to 25 mg.[51] Its presumed mechanism of action is reduction of noradrenergic transmission.[51] In a more recent study, use of prazosin among veterans with chronic PTSD did not improve nightmares or sleep quality compared to placebo, though the study population may have selected patients who were less likely to respond to prazosin.[52] In light of this data, newer Veterans Administration guidelines cite prazosin effects to be similar to placebo and state there is insufficient evidence to recommend use of this agent in this population[5] whereas other studies and guidelines continue to support prazosin use, when indicated.[53,54] Other pharmacologic options for persistent sleep disturbances are limited. Medications with sedative properties (eg, nefazodone, imipramine, mirtazapine, phenelzine, or second-generation antipsychotics) may be considered depending upon individual comorbidities.[5,39] Other therapies that may be useful for PTSD-related nightmares are discussed in the American Academy of Sleep Medicine Position Paper.[55]

Antiseizure medications can assist in reducing impulsive anger and can also be used in patients with comorbid bipolar disorder; however, the use of an antiseizure medication is not recommended as monotherapy. Some data support efficacy of lamotrigine and topiramate, though overall data with antiseizure medications are inconsistent.[4,5,32,39]

Dosage and Administration

Acute Phase

③ Symptoms of PTSD respond slowly to pharmacotherapy, and some patients never experience full resolution, therefore SSRIs should be started 3 to 4 weeks after exposure to a trauma in patients with no improvement in their acute stress response. The initiation of an SSRI should be at a low dose with gradual titration upward as tolerated to moderate to high doses. Eight to 12 weeks is an appropriate duration of antidepressant therapy to determine response.[4,38,42]

Continuation Phase

Many patients undergo psychotherapy during the continuation phase of therapy, and medication dosages can vary as patients deal with past traumatic experiences. During this phase, symptoms continue to improve. Six-month relapse prevention trials in patients responsive to fluoxetine or sertraline indicate low rates of relapse with SSRI therapy compared with placebo.[42]

Maintenance and Discontinuation

④ Patients with PTSD who respond to pharmacotherapy should continue treatment for at least 12 months.[4,38,42,56] If residual symptoms persist, medication therapy should be continued. The decision about when to discontinue therapy is based on response, relapse prevalence, presence of ongoing stresses, adverse effects, and patient preference. Once the decision is made to discontinue therapy, the medications should be withdrawn and tapered slowly over a period of at least 1 month to reduce the potential for relapse.

Special Populations

Adults are not the only population susceptible to PTSD, as children who experience stress and trauma (eg, sexual or physical abuse or loss of a parent) are predisposed to develop mood and anxiety disorders. For this patient population, SSRIs are the initial pharmacologic agents of choice[57]; however, psychotherapy (eg, TFCBT) is also a treatment option and studies are ongoing to assess the comparative efficacy and acceptance of psychotherapies for PTSD among children and adolescents.[58,59]

Patients with PTSD and co-occurring unhealthy substance use disorders also warrant careful consideration given the greater risk for attempted suicide.[60] Guidelines suggest this population may benefit from concurrent treatment of both PTSD and substance use disorder and trauma-focused therapies have demonstrated improvement in PTSD symptoms in this population.

Choosing Pharmacotherapy

The choice of pharmacotherapy should be individualized to the patient's presenting symptoms. Selection of SSRI or venlafaxine monotherapy is based on the patient's history of prior response, safety, and side-effect tolerability and is largely a trial-and-error process.[61] When selecting an agent, the clinician should consider the potential for adverse consequences in patients with comorbid conditions (eg, anticholinergic effects and weight gain with paroxetine in patients with benign prostatic hypertrophy or obesity) or adverse effects (eg, insomnia with fluoxetine in patients with sleep difficulties). Increased risk of suicidality should be considered in patients taking antidepressants who are under 25 years of age.

Currently there are no guidelines or articles that specifically address the use of pharmacogenomics testing in PTSD.[43] However, there are data that can help guide medication selection based on specific gene drug pairs for many of the antidepressants used in treating PTSD.[61] The Clinical Pharmacogenomics Implementation Consortium (CPIC) is a valuable resource for understanding dosing recommendations for these various drug and gene combinations.[62]

EVALUATION OF THERAPEUTIC OUTCOMES

During the acute phase of therapy, patients should be seen frequently. During months 3 to 6 of therapy, the patient can usually be seen monthly, and in months 6 to 12, visits can usually be extended to every 2 months. On each visit the patient should be asked about previously identified PTSD target symptoms as well as other symptoms including insomnia, suicidal ideation, anger outbursts, irritability, psychosis, ongoing trauma, and disability. The Clinician-Administered PTSD Scale (CAPS) can be used by the clinician to assess symptom severity at each visit.[5] Remission in patients with PTSD is defined as a 70% or greater reduction in symptoms. A 50% or greater reduction in symptoms is considered adequate response, while a 25% to 50% reduction in symptoms is considered partial response. Before deciding that a patient is not responsive to pharmacotherapy, the clinician should ensure patient adherence and that the medication trial has been adequate in both dose and duration.

Many patients with PTSD are sensitive to the adverse effects of medications and should be monitored carefully for adverse reactions that can delay dose escalation or cause the patient distress. See Chapter 88 for details on monitoring antidepressants. Routine assessment of the metabolic profile is necessary if a second-generation antipsychotic is used concurrently (see Chapter 87).[4,33] When pharmacotherapy is discontinued, patients should be seen more frequently and monitored carefully for signs of relapse or withdrawal.

TREATMENT—OBESESSIVE COMPULSIVE DISORDER

Desired Outcomes

Major goals of therapy for OCD include reduction in the frequency and severity of obsessive thoughts and time spent performing compulsive acts.[63] Treatment for OCD generally does not eliminate obsessions or compulsions, but patients can feel remarkably improved with partial resolution of symptoms. Patients typically experience waxing and waning symptoms with only 20% going on to achieve full remission.[1] Optimal treatment increases psychosocial and occupational functioning and improves overall QOL.[63] Efforts should be made to minimize adverse drug events and prevent drug interactions.

General Approach to Treatment

It is important at the outset of therapy to identify and document the specific target symptoms for pharmacotherapy. Rating scales can be used to measure symptom severity at baseline and during treatment to ascertain the degree of improvement. The Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) is the most widely used clinician-administered OCD rating scale. A QOL scale can assist the clinician in identifying other areas to target for treatment (eg, depression and reduced physical well-being).[63,64]

The FDA has approved five antidepressants for the management of OCD: clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline. First-line therapy for OCD includes CBT alone, SSRI monotherapy, or the combination of CBT and an SSRI.[63,64] The choice of therapy is based on clinical judgment, symptom severity, and patient preferences[63]; however, CBT has been largely found to be more effective compared to SSRI monotherapy.[65,66] Patients unable to participate in CBT or with a prior history of medication therapy response should be treated with SSRI monotherapy.[63] Combined CBT and SSRIs is recommended in patients who do not respond to SSRI monotherapy or in those with severe OCD. If a combination of CBT and an SSRI at maximum tolerated dose is unsuccessful, subsequent management options include intensifying CBT, switching to an alternate SSRI, switching to clomipramine, or augmenting with either clomipramine or an antipsychotic.[12,27]

Table 91-3 provides a summary of key points from the treatment guidelines for OCD. Although some OCD symptoms can improve over the first 2 to 6 weeks of therapy, an adequate trial is considered 8 to 12 weeks.[12,26,67]

TABLE 91-3

Summary of Key Points in Treatment Guidelines for OCD

Recommendation	Comments
First-Line Treatments	
CBT alone	13-20 sessions
SSRI alone	8-12 weeks, at least 4-6 weeks at maximum tolerated dose
CBT + SSRI	If monotherapy with CBT or SSRI alone does not provide adequate response, combination therapy with CBT + SSRI should be tried before augmentation with another pharmacologic agent
Second-Line Treatments	
Switch to another SSRI or clomipramine	
Augmentation with antipsychotic	Aripiprazole and risperidone are preferred second-generation antipsychotics for OCD treatment
Switch to venlafaxine	
Third-Line Treatments	
Switch to another antipsychotic augmenting agent	
Switch to duloxetine or mirtazapine	
Augmentation of SSRI with clomipramine	Citalopram, escitalopram, and sertraline have less risk to cause clinically significant drug-drug interactions with clomipramine
Maintenance and Discontinuation Phase	
After 1-2 years, gradual taper over several months	
Periodic CBT booster sessions for 3-6 months	

CBT, cognitive behavioral therapy; OCD, obsessive-compulsive disorder; SSRI, selective serotonin reuptake inhibitor.

Data from References 4 and 63.

Nonpharmacologic Therapy

5 Cognitive behavioral therapy with behavioral techniques (eg, exposure and response prevention [ERP]) is the most common initial nonpharmacologic treatment of choice in OCD and is largely considered to be more efficacious than pharmacotherapy.[12,36,66,68] It is preferred for motivated patients, particularly children and adolescents, with both mild OCD symptoms and psychiatric comorbidities, and in those with a desire to avoid medications.[11,12,63,68] Additionally, CBT offers flexibility in dosing (eg, weekly or intensively) and format (eg, individual, group, with or without family involvement).[12,68] Furthermore, family psychoeducation to minimize family accommodation (eg, adaptation of family routines that facilitate ritualistic compulsions) should be integrated into treatment plans to minimize the patient's functional impairment, family conflict/distress, and disruptive behavior to facilitate improved treatment response.[69]

Other nonpharmacologic options for OCD include neuromodulatory approaches (eg, deep brain stimulation [DBS], TMS, and electroconvulsive therapy [ECT]) and ablative neurosurgery for severely symptomatic patients as a treatment of last resort.[12,27] DBS is FDA-approved as a humanitarian device for severe, treatment-resistant OCD.[64] Despite the FDA clearing one TMS device for treatment of OCD, the significant heterogeneity across published study designs and outcomes calls for careful interpretation and application.[70] Preliminary data regarding ECT are promising but still inconclusive to support routine use.[27] While these alternatives may be effective in some patients, uncertainties regarding optimal stimulation site and settings for these neuromodulatory approaches likely contribute to heterogeneity in outcomes.

Pharmacologic Therapy

6 7 As a class, SSRIs are the drugs of choice for patients with OCD,[63] and while not all are FDA-approved, citalopram and escitalopram have also shown efficacy in reduction of OCD symptoms.[12,66] Clomipramine, a TCA with strong 5-HT reuptake inhibition, is a second-line treatment option.[71] Benzodiazepines should not be used to treat OCD-related obsessions and compulsions.[27,63]

Antidepressant Medications

Current evidence indicates that 5-HT is important for the antiobsessional effects of these medications.[72] Pharmacologically, SSRIs and clomipramine inhibit 5-HT reuptake into the presynaptic neuron, making more 5-HT available to postsynaptic receptors and reducing formation of the 5-HT metabolite 5-hydroxyindoleacetic acid. Although other nonclomipramine TCAs (eg, amitriptyline, imipramine, and nortriptyline) inhibit 5-HT reuptake, they are less potent and selective. Prolonged exposure to increased amounts of 5-HT after chronic antidepressant treatment (2-3 weeks) leads to altered responsiveness of postsynaptic 5-HT receptors or presynaptic autoregulatory receptors that govern 5-HT release in specific brain regions. An improvement in obsessional symptoms may correlate with plasma concentrations of clomipramine but not desmethylclomipramine, the metabolite of clomipramine with less selectivity for 5-HT reuptake inhibition.[73]

Most experts agree that SSRIs are better tolerated than clomipramine.[12] Table 91-5 details the monitoring of SSRI and clomipramine pharmacotherapy in patients with OCD. Clomipramine is more likely to cause sedation, anticholinergic side effects and weight gain, however, is less likely than SSRIs to cause insomnia, akathisia, nausea, and diarrhea. Regardless of the specific medication used, antidepressant side effects can be dose related and worse with faster dose escalation.

The SSRIs are effective in the treatment of OCD with almost half (40%-60%) of patients achieving a response.[12] Well-designed trials comparing these medications with placebo in head-to-head comparative trials, and meta-analyses have established that fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram are equally effective.[27,66] However, the literature is conflicting as to whether clomipramine is more effective than the SSRIs.[12,27,66]

Venlafaxine and duloxetine, 5-HT and NE reuptake inhibitors, and mirtazapine may also be effective for OCD.[27] Therefore, these antidepressants can be considered second- or third-line therapy options.[4] See Table 91-3.

Pharmacokinetics

Clomipramine is rapidly absorbed after oral administration[71] with maximum plasma concentrations occurring within 2 to 6 hours. Clomipramine is highly protein-bound (97%) in the blood and has a half-life of 19 to 37 hours. It is metabolized to an active metabolite, desmethylclomipramine, which inhibits NE reuptake. See Table 91-4 for information on monitoring clomipramine plasma levels. The pharmacokinetics of SSRIs is discussed in Chapter 88. It is important to note that since clomipramine and the SSRIs are extensively metabolized in the liver, patients with significant liver disease should be prescribed these medications cautiously and in lower doses than those without liver disease. Additionally, increased plasma concentrations of paroxetine occur in subjects with renal impairment necessitating a reduced initial dose.[40] For older patients, little information is available regarding pharmacokinetic changes, therefore medication selection should be based on history of response and adverse effect profile, with treatment initiated at low dose, which is then increased slowly, with vigilant monitoring for adverse effects.[38,63]

Adverse Effects

When selecting pharmacotherapy, the clinician should consider medication specific adverse effects such as QTc prolongation risk with citalopram and escitalopram; anticholinergic effects and weight gain risk (eg, with paroxetine in patients with benign prostatic hypertrophy or obesity); insomnia risk with fluoxetine in patients with sleep difficulties; increased risk of suicidality in patients under 25 years of age taking antidepressants; and drug-drug interaction risk for which citalopram, escitalopram, and sertraline have the least potential for cytochrome P450 (CYP450) isoenzyme inhibition (see Chapter 88).[27]

Risks to consider with clomipramine include lethality in overdose in patients with suicidal ideation; and anticholinergic effects in patients with constipation, narrow-angle glaucoma, or urinary hesitancy.[71] Clomipramine use is associated with the risk of QTc prolongation when used alone and in combination with other agents that prolong the QTc interval.[71,74] Clomipramine should also be used with caution in patients with a history of cardiovascular disease or conduction abnormalities. Because of sedative and anticholinergic side effects, clomipramine is not usually chosen as first-line therapy for older patients with OCD.[63] The use of antidepressants in older individuals is discussed in Chapter 88.

Dosage and Administration

⑧ Table 91-4 summarizes dosing guidelines for SSRIs and clomipramine. The SSRI dose to achieve response in OCD is often higher than doses used in other indications.[63,64] Data from fixed-dose studies in adults indicate that higher SSRI doses are more efficacious than lower doses, although there is a higher adverse effect burden.[27] However, there are no fixed dose studies to guide clinicians on how high to increase the clomipramine dose. If there is inadequate response to an average antidepressant dose, then it should be incrementally increased to the maximum dose within 5 to 9 weeks from the start of treatment. If there is an inadequate response after 4 to 6 weeks at the maximum dose, then another antidepressant should be tried.[63] Eight to 12 weeks is considered an adequate antidepressant trial for OCD treatment before changing to another agent.

TABLE 91-4

Adult Dosing of Serotonin Reuptake Inhibitors in the Treatment of OCD

Drug	Brand Name	Initial Dose	Usual Range	Comments
Citalopram[a]	Celexa	20 mg daily	20-40 mg daily	Maximum dose is 40 mg in adults daily to prevent QTc prolongation; maximum dose of 20 mg daily in older patients, CYP2C19 poor metabolizers, or use with concurrent moderate-to-strong CYP2C19 inhibitors (eg, cimetidine, omeprazole)
Clomipramine	Anafranil	25 mg daily	100-250 mg daily	Doses up to 300 mg daily may be needed in some patients. Steady state trough plasma levels (clomipramine and desmethylclomipramine) should be <500 ng/mL (mcg/L; ~1.7 µmol/L) to minimize risk of conduction delays and seizures
Escitalopram[a]	Lexapro	10 mg daily	10-20 mg daily	Doses up to 40 mg may be needed in some patients
Fluoxetine	Prozac	20 mg daily	40-60 mg daily	Doses of 80 mg or higher may be needed in some patients
Fluvoxamine	- Luvox - Luvox CR	- 50 mg daily - 100 mg bedtime	- 100-300 mg daily - 100-300 mg daily	
Paroxetine	Paxil, Paxil CR, Pexeva	20 mg daily	40-60 mg daily	Higher doses may be needed in some patients
Sertraline	Zoloft	50 mg daily	50-200 mg daily	Higher doses may be needed in some patients

OCD, obsessive-compulsive disorder.

[a] Not FDA-approved for treatment of obsessive-compulsive disorder. Optimal dosing guidelines are not well established.

Data from References 12,38,40,41,71,75.

TABLE 91-5

Monitoring of Patients Being Treated for OCD

Drug	Adverse Drug Reaction	Monitoring Consideration
Clomipramine	Dry mouth, constipation, nausea, dyspepsia, anorexia, somnolence, tremors, dizziness, nervousness	Assess at every visit, however, tolerance to these adverse events should occur in 2 weeks after treatment is started or a dosage increase is made. New onset adverse events may occur due to drug-drug interactions
	Seizures	Assess if new onset seizures have occurred at each visit
	Orthostatic hypotension, tachycardia, ECG changes	Obtain baseline ECG and vital signs in pediatric patients, patients >40 years, those with cardiovascular disease, or those with other risk factors for QTc prolongation (eg, electrolyte abnormalities, concomitant QTc prolonging medications)
	Suicidality	Obtain at every visit. Highest risk is in patients ≤24 years
	Agranulocytosis, leukopenia	Obtain CBC with differential if patient complains of sore throat, fever
	Weight gain	Obtain vitals (including height and weight) and assess at each visit
SSRIs	Nausea, vomiting, diarrhea, sexual dysfunction, headache, insomnia	Should be assessed at every visit, but generally these adverse events and mild and short-lived. They may reoccur due to a new drug-drug interaction
	Anxiety and agitation	Assess at each visit. May occur in some patients early in treatment
	Discontinuation syndrome	Slowly taper medication to reduce the occurrence of this adverse event. Patient education is key in recognizing its occurrence
	Suicidality	Assess at every visit. Highest risk is in patients ≤24 years
	QTc prolongation	Obtain baseline ECG and electrolytes. Of most concern with citalopram doses over 40 mg daily in adults and 20 mg daily in older patients or in those with risk factors >60 years old, female sex, cardiovascular disease, hypokalemia, hypomagnesemia, or concurrent use of drugs that prolong QTc

Alternative Drug Treatments

Augmentation with Antipsychotics

⑨ Augmentation of SSRI treatment with low-to-moderate doses of antipsychotics may be helpful,[12,27,76] and should be considered for patients with tic-related OCD, comorbid psychosis, and treatment-refractory symptoms. One-third of patients with treatment-refractory OCD respond to antipsychotic augmentation.[27] A recent meta-analysis found greater effect sizes for aripiprazole, haloperidol, and risperidone whereas olanzapine, paliperidone, and quetiapine failed to differentiate from placebo; however, quetiapine and olanzapine have been associated with at least one positive result from a randomized controlled trial.[77] First-generation antipsychotics, such as haloperidol, are less preferred given risk of extrapyramidal symptoms. As the long-term use of second-generation antipsychotic augmentation results in higher rates of adverse effects (eg, weight gain, increased blood glucose, lipid abnormalities), treatment should be discontinued if no benefits have been observed after 6 to 10 weeks.[27] Monitoring of antipsychotics can be found in Chapter 87.

Novel Augmentation Strategies

While augmentation with antipsychotics has the most evidence,[76] recent studies have examined novel augmentation approaches using glutamatergic agents (eg, *N*-acetylcysteine, lamotrigine, memantine, minocycline, riluzole, and topiramate) and ondansetron with initial promising results.[12,77] Some experts may prefer a trial of glutamatergic agents relative to antipsychotics to avoid antipsychotic-related adverse effects. Using D-cycloserine to augment ERP in patients with refractory OCD has had mixed results; further research is needed to identify patient and treatment characteristics that may differentially moderate response.[78]

Special Populations

Pregnancy

OCD may be triggered during the peripartum or postpartum period.[20] Risk–benefit analysis should be made by practitioners when deciding to use pharmacotherapy options during pregnancy.[63,79] The use of antidepressants in pregnancy and lactation is discussed in Chapter 88 and the use of antipsychotics in pregnancy and lactation is discussed in Chapter 87. Chapter 99 also discusses pregnancy and lactation in general.

Children and Adolescents

Younger patients exhibit poorer insight regarding obsessions, have more obsessions involving fear of harm and separation, and possess more rituals involving family members. Similar to adult OCD, CBT including ERP and family members and/or SSRI treatment are considered first-line for pediatric patients depending on illness and patient characteristics.[65,69,74] For mild-to-moderate pediatric OCD, CBT is superior to pharmacotherapy.[65]

Both childhood and adult OCD appear to respond similarly to antidepressant therapy with approximately at 50% response rate being seen during the initial SSRI trial in children. Clomipramine, fluvoxamine, sertraline, paroxetine, and fluoxetine are approved by the FDA for the treatment of OCD in children and adolescents.[63] Importantly, in children, the specific adverse effects of SSRI therapy more likely to occur compared to adults include treatment-emergent suicidal ideation, behavioral activation, and mania. In fact, all antidepressants now include a boxed warning regarding risk for suicide in patients 24 years and younger.[69,76] The risk of suicidality in youth is discussed in Chapter 88. Augmentation of SSRIs with antipsychotics or clomipramine is not well studied in pediatric patients but can be considered for treatment-refractory illness after failed SSRI augmentation with CBT, based on expert opinion and guideline recommendations.[69,74]

Antidepressant Dosing in Children

Pediatric patients often require smaller initial doses of medications (eg, fluoxetine 10 mg daily) compared to adults (eg, fluoxetine 20 mg daily). The starting dose of clomipramine in children is 25 mg daily in divided doses[71] with dose escalations occurring over the first 2 weeks up to 3 mg/kg or 100 mg, whichever is smaller. Over the next several weeks, the dose can be increased up to 3 mg/kg with a maximum of 200 mg daily given once daily at bedtime.

Choosing Pharmacotherapy

The choice of an SSRI for the treatment of OCD is based on history of prior response, safety, and adverse effect tolerability of the patient (see Table 91-5). While all SSRIs are considered equally efficacious, a patient may respond better to one agent over another.[63,66] Therefore, antidepressant treatment decisions should consider patient specific factors, such as previous treatment, family history of medication response, patient preference, and insurance coverage of medications. Currently, there are no guidelines that specifically address the use of pharmacogenomics testing in OCD. However, there are data that can help guide medication selection based on specific gene drug pairs for many of the antidepressants used in treating

OCD. A valuable resource for understanding dosing recommendations for these various drug and gene combinations is CPIC.[62] Use of these guidelines, along with any testing interpretation results, may help reduce the risk of antidepressant specific adverse events, potentially, facilitating successful treatment.

EVALUATION OF THERAPEUTIC OUTCOMES

Target symptoms of OCD should be monitored closely with degree of response being used to indicate a need to modify dosage, change medication, or augment therapy. Rating scales can be used to monitor symptom response to therapy for OCD (eg, Y-BOCS) and changes in QOL.[27,63] Response is often defined by an improvement of 25% to 35% in baseline symptoms whereas remission is defined as a total Y-BOCS score less than 16 (out of a total score of 40), both of which still indicate substantial symptomatology.[27] The clinician should inquire about and address problematic adverse effects, including the emergence of suicidal ideation, reported by the patient, and the amount of time the patient spends obsessing and performing compulsions (see Table 91-5).[63] Additionally, changes in social and occupational functioning should be assessed.

⑩ After patients have responded in the acute phase of treatment, treatment gains are maintained with maintenance-phase strategies.[63] Monthly follow-up visits are recommended for at least 3 to 6 months, and a medication taper can be considered after 1 to 2 years of treatment depending on relapse prevalence, medication adverse effects, and patient preferences.[39,63,74] Treatment discontinuation results in higher relapse rates compared with treatment continuation[56] and medication should not be rapidly discontinued. Booster CBT sessions can reduce the risk of relapse when medication is withdrawn.[63] When making the decision to withdraw medication therapy, the dosage can be decreased by 10% to 25% every 1 to 2 months with careful observation for symptom relapse. However, most patients require lifelong medication therapy given chronicity of symptoms.[56]

CONCLUSION

Beginning with the *DSM-5*, both PTSD and OCD related disorders were removed from the anxiety disorder classification. Neurobiological changes in the HPA axis and the CSTC circuit are largely implicated in PTSD and OCD, respectively. The age of onset of PTSD is variable since it depends on trauma or stressful event exposure though it typically occurs before age 40 years while OCD has a bimodal age of onset peaking in late childhood/adolescence and in early adulthood. Both conditions have effective nonpharmacological methods to reduce symptoms including trauma focused therapy, EMDR for PTSD, and CBT with ERP in OCD. The SSRIs are first-line treatment for both conditions; however, moderate-to-high dose SSRIs are typically needed in OCD treatment. The use of antipsychotics in PTSD is controversial, whereas there is a clearer role for antipsychotic augmentation in OCD treatment. Pharmacotherapy should be continued for at least 1 year in PTSD and 1 to 2 years in OCD.

ABBREVIATIONS

5-HT	serotonin
ASD	acute stress disorder

SELF-ASSESSMENT QUESTIONS

1. Which of the following best describes the pathophysiology of posttraumatic stress disorder (PTSD)?

A. Low concentrations of cortisol

B. High levels of neuropeptide Y

C. Underactive autonomic nervous system

D. Decreased secretion of corticotropin-releasing factor

2. Which of the following is considered an intrusion symptom of PTSD?

A. Irritability or anger outbursts

B. Avoiding feelings about the trauma

C. Recurrent disturbing dreams of the event

D. Inability to recall an important aspect of the event

3. In order to meet the diagnostic criteria for acute stress disorder, symptom resolution occurs by what time period?

A. 3 days

B. 4 weeks

C. 3 months

D. 1 year

4. A 19-year-old college student was sexually assaulted at an off-campus party by an acquaintance 2 months ago. The patient presents to the outpatient clinic with complaints of difficulty falling and staying asleep, irritability, feeling numb, and being easily startled. Other reports include intrusive memories of the event, is missing at least 1 day of school a week, and avoids talking with family and friends about the event. You note on examination a restricted range of affect and nervousness and the patient refuses to talk about the details of the event. PTSD is diagnosed. What is the most appropriate first-line pharmacologic management of this patient?

A. Paroxetine 10 mg every day

B. Olanzapine 5 mg twice daily

C. Diazepam 5 mg three times a day

D. Amitriptyline 10 mg at bedtime

5. Which of the following agents has the most evidence to support its use as an augmenting agent in patients with PTSD who are on antidepressant therapy and continue to complain of impulsive anger?

A. Prazosin

B. Zolpidem

C. Clonazepam

D. Lamotrigine

6. A 41-year-old Marine veteran from the war in Afghanistan was diagnosed with PTSD 6 months ago. The patient has had a reduction in symptoms but continues to complain about memories of witnessing the deaths of three close friends during combat and Afghani children being gunned down by the Taliban. The patient continually blames themselves for the deaths of friends and is estranged from their partner. They are currently on sertraline 100 mg daily and has been on this dose for a month. What is the best recommendation at this time?

A. Add quetiapine 25 mg daily

B. Add phenelzine 15 mg at bedtime

C. Increase sertraline to 150 mg daily

D. Switch to venlafaxine extended-release 37.5 mg daily

7. Which of the following nonpharmacologic treatments is the most effective in the management of PTSD?

A. Relaxation training

B. Deep brain stimulation

C. Electroconvulsive therapy

D. Trauma-focused cognitive behavioral therapy

8. A 29-year-old patient with PTSD is seen in the outpatient clinic for a follow-up appointment. The patient has been on venlafaxine extended-release 225 mg daily for the past 6 months, reports a 75% reduction in symptoms, and has returned to work as a schoolteacher. The patient asks how much longer they should remain on medication. Which of the following minimum durations of time should you discuss with the patient?

A. 3 months

B. 6 months

C. 9 months

D. 12 months

9. Results of neuroimaging studies suggest that there is a dysfunction in which of the following areas of the brain in patients with obsessive-compulsive disorder (OCD)?

A. Nigrostriatal tract

B. Hypothalamic pituitary axis

C. Ventromedial prefrontal cortex

D. Cortical-striatal-thalamic circuit

10. Which of the following is an example of a compulsion that a patient with OCD may report?

A. Repeated thoughts of doubt

B. Repetitive urges to place pens in a proper order

C. Repeating the same verse from the bible silently

D. Recurring thoughts of feeling contaminated after touching objects

11. A nurse practitioner would like to initiate paroxetine in a 20-year-old patient with OCD. Which of the following daily starting doses would you recommend?

A. 20 mg

B. 37.5 mg

C. 50 mg

D. 75 mg

12. An 11-year-old has been diagnosed with OCD. The patient's obsessions involve contamination and the patient's parent reports that the child showers three times a day and is constantly washing hands to the point of cracked and bleeding hands. This is beginning to interfere with the family's routines and the patient's ability to complete schoolwork and homework assignments. The parent requests that the patient be placed on medication. The patient is currently not taking any medications. Which of the following would be the most appropriate recommendation?

A. Risperidone 1 mg 2 times daily

B. Clomipramine 25 mg at bedtime

C. Venlafaxine 25 mg 3 times daily

D. Fluoxetine 10 mg every morning

13. Which of the following is the most effective and least invasive nonpharmacological treatment for OCD?

A. Ablative neurosurgery

B. Deep brain stimulation

C. Exposure and response prevention

D. Trauma-focused cognitive behavioral therapy

14. A 32-year-old individual with a 10-year history of treatment refractory OCD complains of an increase in fears that his child will be hit by a tractor-trailer and die. This has led to the patient literally knocking on wood for up to 2 hours daily. The patient has been on escitalopram 20 mg daily for the past 3 years and lives in a rural area without access to psychotherapy. Which of the following would be the best augmenting agent to try?

A. Quetiapine

B. Haloperidol

C. Venlafaxine

D. Aripiprazole

15. A patient with newly diagnosed OCD has been on citalopram 20 mg daily for the past 3 months with a 50% reduction of symptoms based on the Yale-Brown Obsessive-Compulsive Disorder Scale. The patient inquires as to how much longer it is recommended that they stay on this medication. What is the most appropriate response?

A. 3 days

B. 9 weeks

C. 9 months

D. 3 years

16. Which of the following parameters should be obtained at baseline and checked at each visit in patients maintained on clomipramine 75 mg twice daily for OCD?

A. Weight

B. Blood glucose

C. Electrocardiogram

D. Complete blood count

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** There are many neuroendocrine and neurochemical abnormalities associated with PTSD. Patients with PTSD demonstrate hypersecretion of corticotropin-releasing factor but have subnormal levels of cortisol. Further, studies in nonmilitary patients have identified that lower plasma cortisol concentrations are associated with more severe PTSD symptoms.

2. **C.** Intrusion symptoms are characterized by distressing memories of the trauma. These can take the form of recurrent, distressing dreams or feeling that the trauma is reoccurring and may be associated with a similar physiologic reaction or psychological distress related to the trauma.

3. **B.** To meet diagnostic criteria for acute stress disorder (ASD), symptoms must last for at least 3 days and resolve within a month.

4. **A.** This patient meets diagnostic criteria for a diagnosis of PTSD, including significant impairment; therefore, pharmacotherapy is warranted. Antidepressants, including SSRIs and venlafaxine, are first-line treatment options in PTSD. Further, paroxetine is FDA-approved for the treatment of PTSD.

5. **D.** The addition of an antiseizure medication, such as lamotrigine or topiramate, to augment an antidepressant regimen is reasonable to target impulsive anger. Note: antiseizure medications should not be used as the sole therapeutic agent.

6. **C.** Optimization of the effective antidepressant medication, sertraline, in this case, and titration to an effective and well-tolerated dose should occur prior to augmenting with an additional medication. Further, due to the patient's positive response to sertraline thus far, it would not be appropriate to switch to another medication at this time.

7. **D.** Current guidelines emphasize the utility of trauma-focused cognitive behavioral therapy (TFCBT). Further, prolonged exposure individual trauma-focused psychotherapy in close proximity to the traumatic event resulted in lower rates of PTSD within 6 months. Data also support TFCBT is more effective than stress management or group therapy to reduce symptoms of PTSD.

8. **B.** Since this patient has responded well to venlafaxine extended-release, treatment should continue for at least another 6 months, for a total treatment duration of 1 year. Residual symptoms persist, strengthening the recommendation to continue treatment. With the patient's return to work, additional stressors may occur, further influencing the patient's response to treatment. Once an adequate treatment period has occurred, the medication should be slowly tapered to avoid withdrawal symptoms and reduce the risk for relapse.

9. **D.** Neuroimaging studies suggest that dysfunction in the cortical-striatal-thalamic circuits is responsible for impulsive behavior and inability to regulate socially acceptable behaviors. Drugs that decrease hyperactivity in the cortical-striatal-thalamic circuits decrease symptoms of OCD.

10. **C.** Obsessions are recurrent and persistent thoughts, urges, or images that are experienced as intrusive and unwanted, whereas compulsions are repetitive behaviors or mental acts that an individual feels driven to perform in response to an obsession or according to rules that must be applied rigidly.

11. **A.** Paroxetine 20 mg is the recommended starting dose for OCD treatment as exacerbation of anxiety in the early stages of OCD treatment is uncommon. A usual effective range for paroxetine is 20 to 60 mg daily. Doses of 80 mg or higher may be needed in some patients though they are above the FDA-approved max.

12. **D.** SSRIs are considered first-line treatment for both pediatric and adult OCD. Pediatric patients often require smaller initial doses of medications (eg, fluoxetine 10 mg daily) compared to adults (eg, fluoxetine 20 mg daily).

13. **C.** CBT with behavioral techniques (eg, exposure and response prevention [ERP]) is the most common initial nonpharmacologic treatment of choice in OCD. CBT with ERP is considered a first-line treatment option for both pediatric and adult OCD, especially in mild-to-moderate cases. It may be combined with pharmacologic treatment for moderate-to-severe cases of OCD. CBT is considered superior to pharmacologic interventions.

14. **D.** SSRI augmentation with antipsychotics is effective in one-third of patients with treatment refractory OCD. A recent meta-analysis found greater effect sizes for aripiprazole, haloperidol, and risperidone whereas olanzapine, paliperidone, and quetiapine failed to differentiate from placebo. In general, second-generation antipsychotics are preferred over first-generation antipsychotics for OCD treatment given less risk of extrapyramidal symptoms. Additionally, first-generation antipsychotic effectiveness for OCD treatment is mainly limited to patients with comorbid tics.

15. **C.** Medication taper can be considered after 1 to 2 years of treatment in patients with OCD.

16. **A.** Patient body weight should be assessed at baseline and at every office visit during clomipramine treatment because of its anticholinergic and antihistaminergic receptor activity. While clomipramine is associated with weight gain, it is not known to cause blood sugar abnormalities. Blood dyscrasias (eg, leukopenia, agranulocytosis) are rare so routine monitoring is unnecessary. ECG should be obtained at baseline in pediatric patients, those >40 years old, and those with cardiovascular disease. After obtaining a baseline ECG, follow-up assessments can be obtained as clinically indicated.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 92: Sleep Disorders

John M. Dopp; Bradley G. Phillips

KEY CONCEPTS

KEY CONCEPTS

①Common causes of insomnia include concomitant mental illness, significant psychosocial stressors, alcohol use, caffeine intake, and nicotine use.

②Good sleep hygiene, including relaxing before bedtime, exercising regularly, establishing a regular bedtime and wake-up time, and discontinuing alcohol, caffeine, and nicotine, alone and in combination with pharmacotherapy, should be part of patient education and treatments for insomnia.

③Long-acting benzodiazepines should be avoided in older individuals.

④Benzodiazepine receptor agonist tolerance and physical dependence are avoided by using low-dose therapy for the shortest possible duration.

⑤Obstructive sleep apnea may be an independent risk factor for the development of hypertension. When hypertension is present, it is often refractory to pharmacotherapy until sleep-disordered breathing is alleviated.

⑥Nasal continuous positive airway pressure is the first-line therapy for obstructive sleep apnea, and weight loss should be encouraged in all obese patients.

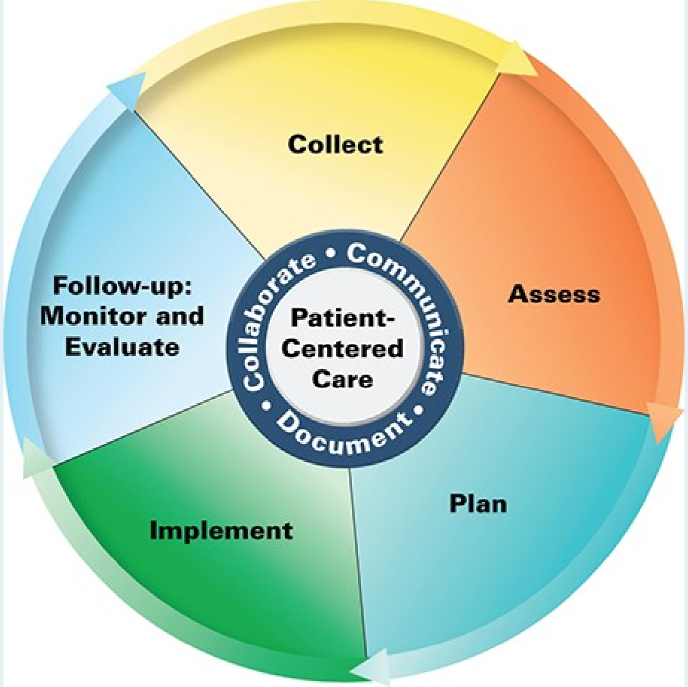
⑦Pharmacologic management of narcolepsy is focused on two primary areas: treatment of excessive daytime sleepiness and rapid eye movement (REM) sleep abnormalities.

⑧Short-acting benzodiazepine receptor agonists, ramelteon, or melatonin taken at appropriate target bedtimes for east or west travel reduce jet lag and shorten sleep latency.

⑨The alpha-2-delta ligands, gabapentin, gabapentin enacarbil, and pregabalin, are standard therapy for chronic restless legs syndrome and have not caused symptom augmentation during chronic therapy.

PATIENT CARE PROCESS

Patient Care Process for Sleep–Wake Disorders



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, concomitant medical conditions, environmental or social stressors)
- Information about nighttime sleep complaints and daytime consequences from patient and bed partner
- Detailed medication history of prescription, over the counter(OTC), and complementary/alternative medication use
- Subjective and objective data about daytime sleepiness, sleep quality, limb movements, snoring, witnessed apneas, and parasomnias
- Information about sleep routine, sleep hygiene, and social history (eg, caffeine, alcohol, and tobacco use)
- Results from sleep testing (if available)

Assess

- Evaluate if individual environmental or social issues are contributing to sleep difficulties.
- Assess medications to determine if any may be contributing to sleep and/or daytime complaints.
- Assess any laboratory or sleep study test results that aid in assessment/treatment of sleep complaints (eg, serum ferritin, TSH, and so on).
- Concomitant mental illness or other medical conditions that should be addressed as part of sleep evaluation (eg, presence of anxiety, depression, chronic pain).

Plan*

- Optimize sleep hygiene and related behaviors (Tables 92-1 and 92-2) that may influence sleep and daytime symptoms.
- For insomnia, if sedative-hypnotic therapy is prescribed, match the agent’s duration of action to sleep complaint (eg, short-duration agents for difficulty initiating sleep and moderate duration agents for difficulty maintaining sleep) (Table 92-3).
- Ensure that lowest doses of medication are used, but if response is inadequate, consider increasing dose or adding complementary medication.

- For narcolepsy or sleepiness disorders, consider use of long-acting stimulants to increase wakefulness throughout the day. Add as needed short-acting stimulants for late afternoon or evening periods requiring wakefulness (Table 92-4).

Implement*

- Provide patient education regarding all elements of treatment plan.
- Use motivational interviewing and coaching strategies to maximize adherence.
- Answer patient questions about medications and potential adverse effects.

Follow-up: Monitor and Evaluate

- Evaluate improvement in the specific sleep complaint (eg, how has therapy affected sleep latency or sleep maintenance?).
- Monitor daytime sleepiness, sleep diaries, and diaries of sleep events (eg, periodic limb movements of sleep [PLMS], hallucinations, snoring, apneas, and so on) and monitor cataplexy and other daytime symptoms to determine if therapy is effective.
- Make appropriate changes to therapy to address inadequately controlled symptoms and reported adverse effects (Tables 92-4 and 92-5).

***** *Collaborate with patients, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Construct a table of medications used for insomnia, list the half-lives of their parent compound, and whether they are used for difficulty initiating or maintaining sleep.

Medication	Parent Medication Half-Life (hours)	Insomnia Use
Amitriptyline	15	Difficulty maintaining sleep
Zaleplon	1	Difficulty initiating sleep

INTRODUCTION

Approximately 70 million Americans suffer with a sleep-related problem, and as many as 60% of those experience a chronic disorder.[1] More than 80% of patients aged 65 years and older report a sleep-related disturbance..[1]

Sleep Cycles

Sleep is divided into two phases: nonrapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. Each night humans typically experience four to six cycles of NREM and REM sleep, with each cycle lasting between 70 and 120 minutes.[2] There are three stages of NREM sleep. Healthy sleep will typically progress through the three stages of NREM sleep prior to the first REM period. From wakefulness, sleep typically progresses quickly through stages 1 and 2. Stage 1 of NREM sleep is the stage between wakefulness and sleep, and individuals describe this experience as being awake, being drowsy, or being asleep. During stage 3 NREM, both metabolic activity and brain waves slow. This slow-wave sleep occurs most frequently early in the sleep period. Stage 3 sleep is called *delta sleep*, as the sleep is characterized by high amplitude and slow activity waves known as delta waves (0.5–3 Hz) with no eye movements and low tonic muscle activity.

REM sleep involves a dramatic physiologic change from NREM sleep to a state in which the brain becomes electrically and metabolically activated.[2] REM occurs in bursts and is accompanied by a 62% to 173% increase in cerebral blood flow, generalized muscle atonia, bursts of bilateral REMs, poikilothermia, dreaming, and fluctuations in respiratory and cardiac rate.[2] REM cycles tend to lengthen in the later stages of the sleep cycle.[2]

Circadian Rhythm

At birth, human infants spend up to 20 hours a day sleeping with differentiation between REM and NREM sleep occurring at 3 to 6 months of age and the ultradian sleep–wake rhythm changing to a circadian pattern by age 3. Key to this is the suprachiasmatic nucleus of the brain which serves as the biologic clock and paces the circadian rhythm; although the length of a day is 24 hours, in environments devoid of light cues, the sleep–wake cycle lasts about 25 hours.[3] Through development from childhood into adolescence, the amount of nightly delta sleep declines and amount of REM sleep increases. In midlife, however, there is a gradual decline in sleep efficiency and sleep time,[2] and older persons have lighter and more fragmented sleep, with intermittent arousals, shifts in the sleep stages, and a gradual reduction of slow-wave sleep.

Neurochemistry

The neurochemistry of sleep is complex, as sleep cannot be localized to either a specific area of the brain or a specific neurotransmitter. Overall, NREM sleep appears to be controlled by the basal forebrain, the lower brain stem to the thalamus, and hypothalamus with numerous neurotransmitters mediating NREM sleep, including γ-aminobutyric acid (GABA) and adenosine.[3] In contrast, REM sleep appears to be turned on by cholinergic cells in the mesencephalic, medullary, and pontine gigantocellular regions and turned off by the dorsal raphe nucleus, the locus coeruleus, and the nucleus parabrachialis lateralis, the latter two of which are primarily noradrenergic. The ascending reticular activating system and the posterior hypothalamus also facilitate arousal and wakefulness[4] through neurotransmitters such as dopamine, which has an alerting effect.[5] Additional neurochemicals involved in wakefulness include norepinephrine and acetylcholine in the cortex, and histamine and neuropeptides such as substance P and corticotropin-releasing factor in the hypothalamus.[5,6]

Polysomnography

Polysomnography (PSG) is the primary method used to assess and record variables that characterize sleep and aid in diagnosis of sleep disorders. As part of this assessment, sleep is typically measured and observed in sleep laboratories using an electroencephalogram, electrooculograms of each eye, electrocardiogram, electromyogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitor. Variables obtained during PSG include sleep onset, arousals, sleep stages, eye movements, leg and jaw movements, arrhythmias, airflow during sleep, respiratory effort, and oxygen desaturations. Additionally, home sleep monitoring that measures variables such as electrocardiogram, oxygen saturation, airflow, and respiratory effort is increasingly used to diagnose sleep apnea.

Classification of Sleep Disorders

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* classifies sleep–wake disorders into 10 categories: (1) insomnia disorder, (2) hypersomnolence disorder, (3) narcolepsy, (4) breathing-related sleep disorders, (5) circadian rhythm sleep disorders, (6) non-REM sleep arousal disorders, (7) nightmare disorder, (8) REM sleep behavior disorder, (9) restless legs syndrome (RLS), and (10) substance- or medication-induced sleep disorder.[7]

Insomnia

Insomnia is one of the most common complaints in general medical practice[8] as it frequently causes distress, due to the fear or a feeling of not being able to fall asleep at bedtime, leading to impaired work-related productivity because of daytime fatigue or drowsiness. Therefore, insomnia disorder is subjectively characterized as trouble initiating sleep, maintaining sleep or waking up early with inability to fall back asleep, that is associated with daytime consequences (insomnia not attributed to environment or limited opportunity for sleep).[7–9] Insomnia is classified as chronic when it has a duration of at least three months, occurring at least three times per week.[7,9]

Primary insomnia usually begins in early or middle adulthood and is rare in childhood or adolescence. Short-term insomnia occurs in 33% to 50% of the adult population,[8] with a year prevalence study of insomnia in the United States reporting that one-third of the individuals surveyed complained of insomnia and 17% reported that the symptoms were serious.[1] Conservative estimates of chronic insomnia range from 9% to 12% in adulthood and up to 20% in older individuals.[1,10] Although young adults are more likely to complain that they have difficulty falling asleep, middle-aged and older adults are more likely to complain that they have middle-of-the-night awakening or early morning awakening. Females complain of insomnia twice as frequently as males and individuals who are older, unemployed, separated, or widowed, and those with a lower socioeconomic status report a significantly higher incidence of insomnia than the general population. Forty per cent of individuals with insomnia also have a concurrent psychiatric disorder (eg, anxiety, depression, or substance use disorder),[11] and a significant percentage of those with insomnia use nonprescription medications or alcohol to self-treat.

Clinical Presentation

Differential Diagnosis

Insomnia is considered to be an endogenous disorder caused by either a neurochemical or a structural disorder affecting the sleep–wake cycle. Individuals with primary insomnia can be light sleepers who are easily aroused by noise, temperature, or anxiety. Primary insomnia is a “hyperarousal state,” in that insomnia patients have increased metabolic rates compared with controls and thus take longer to fall asleep.[2] Comorbid or secondary insomnia is frequently a symptom or manifestation of another medical disorder. Evaluation of individuals with complaints of transient or short-term insomnia should focus on recent stressors, such as a separation, a death in the family, a job change, or college exams.

① Chronic insomnia is frequently comorbid with psychiatric or medical conditions. A complete diagnostic examination should be completed in these individuals and should include routine laboratory tests, physical and mental status examinations, as well as ruling out any medication- or substance-related causes.[12] Other sleep disorders that can have a similar presentation should be ruled out, including restless legs syndrome (RLS) periodic limb movement disorder, and sleep apnea. Common causes of insomnia are listed in Table 92-1.

TABLE 92-1

Common Etiologies of Insomnia

Situational
• Work or financial stress, major life events, interpersonal conflicts
• Jet lag or shift work
Medical
• Cardiovascular (eg, angina, arrhythmias, heart failure)
• Respiratory (eg, asthma, sleep apnea)
• Chronic pain
• Endocrine disorders (eg, diabetes, hyperthyroidism)
• Gastrointestinal (eg, gastroesophageal reflux disease, ulcers)
• Neurologic (eg, delirium, epilepsy, Parkinson disease)
• Pregnancy
Psychiatric
• Mood disorders (eg, depression, mania)
• Anxiety disorders (eg, generalized anxiety disorder, obsessive-compulsive disorder)
• Substance use disorders (eg, alcohol or sedative-hypnotic withdrawal)
Pharmacologically induced
• Antiseizure medications
• Central adrenergic blockers
• Diuretics
• Selective serotonin reuptake inhibitors
• Steroids
• Stimulants

Treatment

Desired Outcomes

The goals of treatment for insomnia are to correct the underlying sleep complaint, consolidate sleep, improve daytime functioning and sleepiness, and avoid adverse effects from selected therapies. Pharmacotherapy should be used in the lowest possible dose, for the shortest possible time period.

General Approach to Treatment

Therapeutic management of insomnia is initially based on whether the individual has experienced a short-term or chronic sleep disturbance. Clinical history should assess the onset, duration, and frequency of the symptoms; effect on daytime functioning; sleep hygiene habits; and history of previous symptoms or treatment.[13] Management of all patients with insomnia should include identifying and correcting the cause, patient education on sleep hygiene, and stress management. Any unnecessary pharmacotherapy that may worsen insomnia should be eliminated.[10] Short-term insomnia, which generally occurs as a result of acute stressors, is expected to resolve quickly and should be treated with good sleep hygiene and careful use of sedative-hypnotics.[11,13] Chronic insomnia requires careful assessment for possible underlying medical causes, nonpharmacologic approaches, and careful use of sedative-hypnotics.[12]

Nonpharmacologic Therapy

② In many cases, insomnia can be treated without sedative-hypnotics. Education about normal sleep and habits for good sleep hygiene is important for all patients with insomnia. Nonpharmacologic interventions for insomnia frequently consist of short-term cognitive behavioral therapies, most commonly stimulus control therapy, sleep restriction, relaxation therapy, cognitive therapy, paradoxical intention, biofeedback, and education on good sleep hygiene (Table 92-2).[10,14] In patients aged 55 years and older, cognitive behavioral therapy may be more effective than pharmacologic therapy at improving certain measures of insomnia.[15,16]

TABLE 92-2

Nonpharmacologic Recommendations for Management of Insomnia

Stimulus control procedures

1. Establish regular time to wake up and to go to sleep, including weekends.
2. Sleep only as much as necessary to feel rested.
3. Go to bed only when sleepy. Avoid long periods of wakefulness in bed. Use the bed only for sleep or intimacy; do not read or watch television in bed.
4. Avoid trying to force sleep; if you do not fall asleep within 20-30 minutes, leave the bed and perform a relaxing activity (eg, read, listen to music) until drowsy. Repeat this as often as necessary.
5. Avoid blue spectrum light from television, smart phones, tablets, and other mobile devices.
6. Avoid daytime naps.
7. Schedule worry time during the day. Do not take your troubles to bed.

Sleep hygiene recommendations

1. Exercise routinely (eg, three to four times weekly) but not close to bedtime because this can increase wakefulness.
2. Create a comfortable sleep environment by avoiding temperature extremes, loud noises, and illuminated clocks in the bedroom.
3. Discontinue or reduce the use of alcohol, caffeine, and nicotine.
4. Avoid drinking large quantities of liquids in the evening to prevent nighttime trips to the restroom.
5. Do something relaxing and enjoyable before bedtime.

Pharmacologic Therapy

Antihistamines

Antihistamines exhibit sedating properties and are included in many nonprescription sleep agents. They are effective in the treatment of mild insomnia and generally safe.[13] Diphenhydramine and doxylamine are available in OTC formulations. However, patients quickly experience tolerance to sedative effects, and increasing the dose will not produce a linear increase in response. Antihistamines are considered to be less effective than benzodiazepines, and they have the disadvantages of anticholinergic adverse effects, which are especially troublesome in older individuals.[13,17]

Sedating Antidepressants

For patients with nonrestorative sleep who should not receive benzodiazepines, antidepressants may be an alternative treatment, especially those who have depression, pain, or a history of, or at risk for a substance use disorder. Using antidepressants for insomnia without depression is common but not well studied, and the doses used for treating insomnia are not effective antidepressant doses.[9,13,14] However, low-dose doxepin (3-6 mg) is FDA-approved for the treatment of sleep maintenance insomnia. Other sedating antidepressants such as amitriptyline, doxepin, and nortriptyline are effective in inducing sleep continuity, although daytime sedation and adverse effects can be significant.[9,13] Anticholinergic activity, adrenergic blockade, and cardiac conduction prolongation can be problematic, especially in older individuals and in overdose situations.[9] Mirtazapine is a sedating antidepressant that may help patients sleep, but it may also cause daytime sedation and weight gain.

Trazodone is popular for the treatment of insomnia in patients prone to substance use disorder or in patients with selective serotonin reuptake inhibitor and bupropion-induced insomnia, as physical dependence is not a problem with trazodone.[11] Trazodone in doses of 25 to 100 mg at bedtime is sedating and can improve sleep continuity.[11] Adverse effects associated with trazodone use include carryover sedation and α-adrenergic blockade and orthostasis, which can occur at any age, but it is more dangerous in older individuals. Priapism is a rare but serious adverse effect.[18]

Dual Orexin Receptor Antagonists

Suvorexant and lemborexant are dual orexin A and orexin B receptor antagonists (DORA) that instead of inducing sleepiness, similar to most treatments for insomnia, turns off wake signaling. Suvorexant doses of 10 to 20 mg and lemborexant doses of 5 to 10 mg, at bedtime are indicated for difficulty initiating and maintaining sleep. The most commonly reported adverse effect with DORA use is somnolence, and patients should be counseled that sleep paralysis, cataplexy, and other narcolepsy-like symptoms may rarely occur.[19] Caution should be used in patients with depression as DORA use can worsen mood and trigger thoughts of suicide in a dose-dependent manner.

Melatonin Receptor Agonists

Ramelteon is a melatonin receptor (MT) agonist approved for the treatment of sleep-onset insomnia. It is selective for the MT1 and MT2 melatonin receptors that are thought to regulate the circadian rhythm and sleep onset. The recommended dose is 8 mg taken at bedtime to induce sleep, and although generally well tolerated, the most common adverse events reported are headache, dizziness, and somnolence. Ramelteon is not a controlled substance and can be a viable option for patients with a history of, or at risk for a substance use disorder; however, patients may not feel that it is as effective, as it does not cause the acute drowsiness associated with other insomnia agents. It does, however, effectively treat sleep-onset difficulties in patients with chronic obstructive pulmonary disease and sleep apnea.[20,21]

Miscellaneous

Valerian is a herbal sleep remedy that is purported to effectively treat insomnia but is not recommended by American Academy of Sleep Medicine based on a lack of high quility evidence supporting its use.[8] The mechanism of action is not fully understood but may involve increasing concentrations of GABA. Doses range from 300 to 600 mg. Although frequently used by patients to help with sleep, melatonin has almost no use for treatment of insomnia.

Benzodiazepine Receptor Agonists

The most commonly used treatments for insomnia have been the benzodiazepine receptor agonists (BZDRAs) which are FDA-labeled for the treatment of insomnia (Table 92-3). The Food and Drug Administration (FDA) requires BZDRA labeling to include a caution regarding anaphylaxis, facial angioedema, and complex sleep behaviors (eg, sleep driving, phone calls, sleep eating, and so on). The BZDRAs consist of the newer nonbenzodiazepine $GABA_A$ agonists and the traditional benzodiazepines. All BZDRAs bind to $GABA_A$ receptors in the brain, resulting in agonist effects on GABAergic transmission and hyperpolarization of neuronal membranes. Traditional benzodiazepines have sedative, anxiolytic, muscle relaxant, and antiseizure medication properties; newer nonbenzodiazepine GABA agonists possess only sedative properties.

TABLE 92-3

Pharmacokinetics of Benzodiazepine Receptor Agonists

Generic Name (Brand Name)	t_{max} (hours)[a]	Half-Life[b] (hours)	Daily Dose Range (mg)	Metabolic Pathway	Clinically Significant Metabolites
Estazolam (ProSom)	2	12-15	1-2	Oxidation	–
Eszopiclone (Lunesta)	1-1.5	6	2-3	Oxidation	–
				Demethylation	
Flurazepam (Dalmane)	1	8	15-30	Oxidation	Hydroxyethylflurazepam, flurazepam aldehyde
				N-dealkylation	*N*-desalkylflurazepam[c]
Quazepam (Doral)	2	39	7.5-15	Oxidation, *N*-dealkylation	2-Oxo-quazepam, *N*-desalkylflurazepam[c]
Temazepam (Restoril)	1.5	10-15	15-30	Conjugation	–
Triazolam (Halcion)	1	2	0.125-0.25	Oxidation	–
Zaleplon (Sonata)	1	1	5-10	Oxidation	–
Zolpidem (Ambien; Intermezzo)	1.6	2-2.6	1.75-10[d]	Oxidation	–

[a] Time to peak plasma concentration.

[b] Half-life of parent medication.

[c] *N*-desalkylflurazepam, mean half-life 47 to 100 hours.

[d] Oral and sublingual dosing 5 to 10 mg; sublingual tablets for middle-of-the-night dosing 1.75 to 3.5 mg (1.75 for females, 3.5 for males).

Benzodiazepines relieve insomnia by reducing sleep latency and increasing total sleep time by increasing stage 2 sleep while decreasing delta sleep.[11] Benzodiazepine hypnotics should not be prescribed for individuals who are pregnant or who have untreated sleep apnea or a history of substance use disorder, and patients should be instructed to avoid alcohol and other central nervous system (CNS) depressants.

Adverse effects

Adverse effects are dose dependent and vary according to the pharmacokinetics of the individual benzodiazepine. High doses with long or intermediate elimination half-lives have a greater potential for producing daytime sedation, psychomotor incoordination, and cognitive deficits. Most traditional benzodiazepines maintain hypnotic efficacy for 1 month. However, tolerance can develop with time.

Anterograde amnesia, an impairment of memory and recall of events occurring after the dose is taken, has been reported with most BZDRAs, and is more likely to occur with short-acting agents.[11] Additionally, after abrupt discontinuation of BZDRAs, rebound insomnia, characterized by increased wakefulness beyond baseline amounts, may occur and last for a few nights. Therefore, the lowest effective dosage should be used to minimize rebound insomnia and avoid adverse effects on memory.

③ Benzodiazepine half-lives are prolonged in older patients, increasing the potential for medication accumulation and the incidence of CNS adverse effects, including prolonged sedation and cognitive and psychomotor impairment. BZDRAs with long elimination half-lives (eg, flurazepam and quazepam) are generally not first-line agents in older patients. Benzodiazepine use is also associated with increased risk of falls and hip fractures in older individuals, but since insomnia itself increases fall and fracture risk, it is unclear if benzodiazepines increase risk independent of sleep problems.[22]

Nonbenzodiazepine GABA$_A$ Agonists

Zolpidem, zaleplon, and eszopiclone are nonbenzodiazepine hypnotics that selectively bind to GABA$_A$ receptors and effectively induce sleepiness. Zolpidem has a duration of action of 6 to 8 hours[23] and is comparable in efficacy to benzodiazepine hypnotics, in that it is effective in reducing sleep latency and nocturnal awakenings, and increasing total sleep time. It does not have significant effects on next-day psychomotor performance. Sustained-release, sublingual, and reduced-strength (1.75 and 3.5 mg) formulations of zolpidem are available and are used to increase total sleep time, to reduce sleep latency, and for middle-of-the-night rescue dosing, respectively.

Zolpidem is less disruptive of sleep stages than benzodiazepines and adverse effects include drowsiness, amnesia, dizziness, headache, and gastrointestinal complaints, which are dose-related.[23] Sleep eating during zolpidem therapy can result in significant weight gain. The recommended daily dose of zolpidem is 10 mg in male patients, or 5 mg in female patients, older patients, and those with hepatic impairment. Because food decreases its absorption, zolpidem should be taken on an empty stomach.[24]

Zaleplon has a rapid onset of action with a half-life of 1 hour, and is metabolized to inactive metabolites.[25] It is effective in decreasing time to sleep onset but not for reducing nighttime awakening or for increasing total sleep time.[26] Because of its short half-life, zaleplon has no effect on next-day psychomotor performance and can be used as a sleep aid for middle-of-the-night awakenings.[27] The recommended dose is 10 mg in adults and 5 mg in older individuals.[25] The most common adverse effects with zaleplon are dizziness, headache, and somnolence. There are two interactions of note: zaleplon plasma levels increase when combined with cimetidine and decrease with rifampin.[23]

Eszopiclone is effective in reducing time to sleep onset, wake time after sleep onset, and number of awakenings, and increasing total sleep time and sleep quality. Eszopiclone's duration of action is up to 6 hours.[28] It can be a good option for treatment of sleep maintenance insomnia or early morning awakenings. The most common adverse effects with eszopiclone are somnolence, unpleasant taste, headache, and dry mouth.[28] Eszopiclone is labeled for long-term use and may be taken nightly for up to 6 months.[28,29]

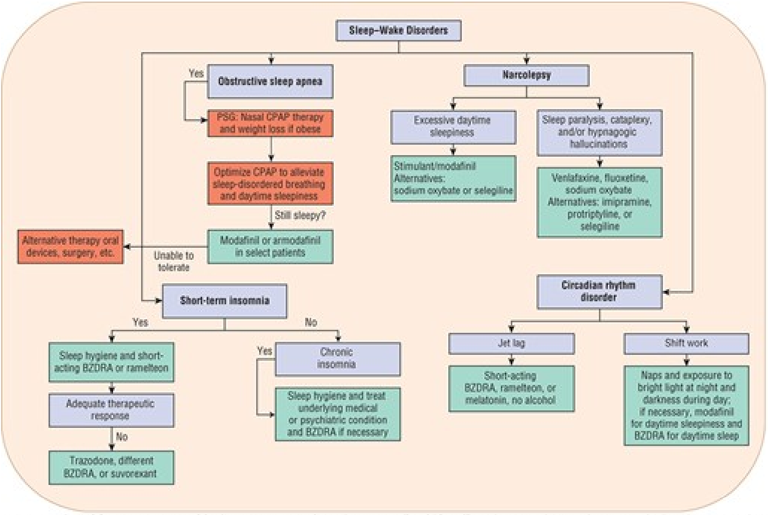
In general, nonbenzodiazepine hypnotics seem to be associated with less physical withdrawal, tolerance, and rebound insomnia than benzodiazepine hypnotics. None of the nonbenzodiazepine GABA$_A$ agonists have significant active metabolites.

Evaluation of Therapeutic Outcomes

An algorithm for the evaluation and treatment of sleep–wake disorders is shown in Fig. 92-1. Patients with short-term or chronic insomnia should be evaluated after 1 week of therapy to assess for medication efficacy, adverse effects, and adherence to nonpharmacologic recommendations. For the treatment of insomnia, the choice of a particular BZDRA can be based on its pharmacokinetic profile. When used as a single dose, the extent of distribution and elimination half-life are important in predicting the duration of action. However, after multiple doses, the elimination half-life and formation of active metabolites determine the extent of medication accumulation and resultant clinical effects.[11] Advanced age, liver dysfunction, and medication interactions can prolong medication effects. The pharmacokinetic profiles of BZDRAs are summarized in Table 92-3.

FIGURE 92-1

Algorithm for treatment of sleep and wake disorders. (BZDRA, benzodiazepine receptor agonist; CPAP, continuous positive airway pressure) *(Adapted, with permission, from Reference 70.)*



Sleep–Wake Disorders
Yes
Obstructive sleep apnea
PSG: Nasal CPAP therapy and weight loss if obese
Optimize CPAP to alleviate sleep-disordered breathing and daytime sleepiness
Still sleepy?
Modafinil or armodafinil in select patients
Unable to tolerate
Alternative therapy oral devices, surgery, etc.
Narcolepsy
Excessive daytime sleepiness
Stimulant/modafinil Alternatives: sodium oxybate or selegiline
Sleep paralysis, cataplexy, and/or hypnagogic hallucinations
Venlafaxine, fluoxetine, sodium oxybate Alternatives: imipramine, protriptyline, or selegiline
Short-term insomnia
Yes
No
Sleep hygiene and short-acting BZDRA or ramelteon
Adequate therapeutic response
No
Trazodone, different BZDRA, or suvorexant
Yes
Chronic insomnia
Sleep hygiene and treat underlying medical or psychiatric condition and BZDRA if necessary
Circadian rhythm disorder
Jet lag
Short-acting BZDRA, ramelteon, or melatonin, no alcohol
Shift work
Naps and exposure to bright light at night and darkness during day; if necessary, modafinil for daytime sleepiness and BZDRA for daytime sleep

Patients should be instructed to keep a sleep diary that includes daily recording of bedtime, wake time, latency of sleep onset, number and duration of awakenings, medication ingestion, naps, and an index of sleep quality. For patients with chronic insomnia, possible medical, psychiatric, and pharmacologic causes should be identified and managed.[11] Patients with insomnia should receive education about possible medication adverse effects and their management.

④ Clinicians should educate patients about the concepts of tolerance, physical withdrawal, and rebound insomnia. Tolerance and physical dependence can be avoided by using hypnotics at the lowest possible dose, intermittently, and for the shortest duration possible. Patients should also receive instruction about frequency of medication use and the expected duration of therapy to help prevent development of physical dependence. Withdrawal symptoms can be diminished by tapering the dosage gradually.

SLEEP APNEA

Sleep apnea is a common disease, affecting 20 to 25 million Americans. It has a higher prevalence in males, particularly in African American and Hispanic populations.[30,31] It also occurs in children and adolescents. It is characterized by repetitive episodes of cessation of breathing during sleep followed by blood oxygen desaturation and brief arousal from sleep to restart breathing. As a result, individuals with sleep apnea experience fragmented sleep, poor sleep architecture, and periods of apnea and hypopnea. PSG, or a home sleep study, is used to diagnose and quantify sleep apnea as central, obstructive, or mixed. Central sleep apnea (CSA) involves impairment of the respiratory drive, whereas obstructive sleep apnea (OSA) is caused by upper airway collapse and obstruction. Patients with mixed sleep apnea experience both CSA and OSA. The overall severity of sleep apnea is determined by the number of apnea (total cessation of airflow) and hypopnea (partial airway closure with blood oxygen desaturation) episodes documented by PSG, which is expressed as the respiratory disturbance index (RDI). Patients with mild sleep apnea have an RDI of between 5 and 15 episodes/hour, and those with moderate apnea have an RDI between 15 and 30 episodes/hour, whereas individuals with severe OSA exhibit more than 30 episodes/hour.

OSA is associated with a greater risk for motor vehicle accidents, depression, increased cancer risk, stroke, and cardiovascular disease.[32–35] Therefore, alleviation of sleep-disordered breathing may improve patient outcomes, particularly those related to cardiovascular disease.[35]

Obstructive Sleep Apnea

OSA is characterized by partial or complete closure of the upper airway, posterior from the nasal septum to the epiglottis, during inspiration. The reason for the loss of upper airway patency is not fully understood and is likely caused by several competing factors. Anatomical factors including neck obesity, narrow airway, and fixed upper airway lesions (eg, polyps, enlarged tonsils) can narrow the upper airway. The intraluminal negative pressure generated during each inspiration also promotes collapse of the upper airway that competes with dilating forces, primarily the pharyngeal dilator muscle. Acromegaly, amyloidosis, and hypothyroidism as well as neurologic conditions that impair upper airway muscle tone may cause OSA. The hallmarks of OSA are witnessed apneas, gasping, or both. Other recognized signs, symptoms, and considerations of sleep apnea include obesity, snoring, daytime sleepiness, family history, and hypertension.

⑤ OSA is increasingly linked to cardiovascular and cerebrovascular morbidity and mortality, independent of other risk factors.[35] Individuals with OSA are at risk for developing hypertension, and when hypertension is present, it is often resistant to medication therapy.[36] Alleviation of sleep-disordered breathing with nasal positive airway pressure (PAP) only modestly improves blood pressure (2-3 mmHg), but increased use of PAP correlates with greater blood pressure reduction.[37,38]

Central Sleep Apnea

CSA causes fragmented sleep and consequent daytime somnolence. However, unlike OSA, arousals from sleep are not required to initiate airflow. During PSG, there is an absence of airflow out of the mouth and nose with no activation of the inspiratory muscles. The prevalence of CSA is not well established and is less than OSA. CSA can be idiopathic but more commonly is caused by underlying autonomic nervous system lesions (eg, cervical cordotomy), neurologic diseases (eg, poliomyelitis, encephalitis, and myasthenia gravis), high altitudes, opioid use disorder, and congestive heart failure. For these reasons, potential underlying causes for CSA should be evaluated and treated. For example, worsening CSA in heart failure patients can signal the need to optimize heart failure therapies. Practice parameters for the treatment of CSA have been published by the American Academy of Sleep Medicine.[45]

Treatment

Desired Outcomes

In the absence of an underlying cause (eg, hypothyroidism, acromegaly), alleviation of sleep-disordered breathing and prevention of associated complications are the primary goals of treatment. Nonpharmacologic measures are the treatments of choice. There is no medication therapy for OSA. However, medications that worsen sleep should be avoided. Practice parameters for the medical treatment of OSA have been published by the American Academy of Sleep Medicine.[39]

Nonpharmacologic Therapy

Positive Airway Pressure

⑥ Nasal PAP during sleep is the standard treatment for most patients with OSA. This procedure produces a positive pressure column in the upper airway using room air to maintain patency by using a flexible tube that connects the PAP machine to a mask that covers the nose or nose and mouth.

PAP delivery may be continuous (CPAP), bi-level (providing a reduced applied pressure during expiration), or auto-titrating continuous positive airway pressure therapy (AutoPAP). The AutoPAP machines may be programmed to a pressure range allowing the machine to provide individualized pressure based on breath-to-breath analysis of the necessary pressure to keep the airway open. The CPAP pressure may be identified during PSG as the pressure setting that results in elimination of sleep-disordered breathing up to 20 cm H_2O (2.0 kPa). Alternatively, the CPAP pressure may also be identified as the pressure used by the AutoPAP machine 90% to 95% of the time. Barriers to PAP adherence, such as ill-fitted mask and nasal dryness, can be managed; however, PAP nonadherence for one night results in a complete reversal of the gains made in daytime alertness.[40]

Weight reduction

Obesity can worsen sleep apnea, and weight management should be implemented for all overweight patients with OSA. Additionally, OSA can predispose patients to weight gain, and in obese patients with mild OSA weight loss alone can be effective.[41] Individuals who are morbidly obese and have severe OSA may consider bariatric surgery for weight loss.

Surgery

Surgical therapy (uvulopalatopharyngoplasty) opens the upper airway by removing the tonsils, trimming and reorienting the posterior and anterior tonsillar pillars, and removing the uvula and posterior portion of the palate. Due to the invasive nature of surgical treatment, this is not a first-line option. In very severe cases, a tracheostomy may be necessary. This procedure can be indicated for select individuals who are morbidly obese, have severe facial skeletal deformity, experience severe drops in oxygen saturation (eg, less than 70% [0.7]), or have significant cardiac arrhythmias associated with their OSA.

Other Therapies

For individuals who experience OSA only during certain sleep positions (eg, when lying on their back), positional therapies can be effective alone, but are usually used in conjunction with PAP therapy. Oral appliances can also be used to advance the lower jawbone and to keep the tongue forward to enlarge the upper airway. Alternatively, hypoglossal nerve stimulators that contract the genioglossus muscle during sleep to maintain airway patency are increasingly being used. These therapies should be considered when PAP therapy cannot be tolerated.[42]

Pharmacologic Therapy

The most important pharmacologic intervention for sleep apnea is the avoidance of all CNS depressants (eg, alcohol, hypnotics) and medications that promote weight gain as both of these worsen OSA. The use of CNS depressants is potentially lethal, as it reduces the brain's reflex ability to cause a mini-arousal and resume breathing. In addition, certain CNS depressants can relax airway muscles, promoting upper airway collapse. Medications that can cause rhinopharyngeal inflammation and cough as an adverse effect of therapy (ie, angiotensin-converting enzyme inhibitor) may also worsen sleep-disordered breathing.

There is no pharmacotherapy for OSA. In clinical trials, serotonergic agents (eg, fluoxetine, paroxetine), tricyclic antidepressants (TCAs) (ie, imipramine, protriptyline), respiratory stimulants (eg, theophylline), medroxyprogesterone, and clonidine have not clinically improved severity of OSA. The effects of antihypertensive agents on sleep apnea are inconsistent and are likely not clinically significant.

Wake-promoting medications (eg, modafinil, armodafinil, and solriamfetol) are FDA-approved to improve wakefulness in patients who have residual excessive daytime sleepiness (EDS) while being treated with PAP. Initiation of therapy should be attempted in patients only after PAP therapy has been optimized to alleviate sleep-disordered breathing and EDS. Wake-promoting medications should be avoided in those with concomitant cardiovascular disease. In patients with concurrent rhinitis, nasal steroids are recommended for use along with PAP therapy.[39]

Medication therapy for CSA is limited and is individualized for each patient, based on underlying etiology. Acetazolamide, which induces a metabolic acidosis that stimulates respiratory drive, and theophylline, which improves severity of CSA, have been studied but have minimal effects on clinical variables.[46,47]

Evaluation of Therapeutic Outcomes

Individuals with sleep apnea should be evaluated after 1 to 3 months of treatment for improvement in alertness and daytime symptoms (eg, sleepiness, impaired memory, and irritability) and weight reduction. Individuals experiencing symptoms (eg, daytime sleepiness, snoring, loss of blood pressure control) despite PAP therapy should have repeat evaluation of sleep apnea severity. Symptoms can recur if patients gain weight, requiring a higher-pressure setting. Conversely, PAP pressure settings can be decreased if weight loss is achieved. Patient adherence to PAP therapy can be monitored by assessing the built-in compliance meter, which is also uploaded to a cloud database that measures the hours used at effective pressure and residual apnea occurrence.

NARCOLEPSY

Narcolepsy, which is a severely debilitating neurologic disease that affects between 0.03% and 0.06% of adult Americans,[43] which often goes undiagnosed or misdiagnosed for years. The prevalence is equal or somewhat higher in males compared to females, and it is commonly recognized in the second decade of life and increases in severity through the third and fourth decades.[43] Individuals with narcolepsy complain of EDS, and in the sleep laboratory, exhibit impairment of both the onset and the offset of REM and NREM sleep and have arousals and disturbed sleep during the night.

Narcolepsy is classified as narcolepsy type 1 (narcolepsy with cataplexy) and narcolepsy type 2 (narcolepsy without cataplexy).[9] Four characteristic symptoms differentiate narcolepsy from other sleep disorders and are known as the *narcolepsy tetrad*: EDS, cataplexy, hallucinations, and sleep paralysis. Cataplexy is a sudden bilateral loss of muscle tone of varying severity and duration without the loss of consciousness, which occurs in 60% to 70% of people with narcolepsy.[43] Cataplexy is often precipitated by situations characterized by high emotion (eg, laughter, anger, excitement) and can manifest as subtle changes, such as jaw or head slumping, or severe weakness, such as knee buckling or collapsing to the ground. Cataleptic episodes can be brief, lasting seconds, or can last for several minutes. Sleep paralysis is anepisodic loss of voluntary muscle tone that occurs when the individual is falling asleep or waking where they are conscious but not able to move or speak. Hallucinations while falling asleep (ie, hypnagogic) and on awakening (ie, hypnopompic) are brief, dream-like experiences that intrude into wakefulness and are experienced by nearly 60% of patients with narcolepsy. Unfortunately, these symptoms sometimes lead to an incorrect mental illness diagnosis.[43] Mechanistically, cataplexy, sleep paralysis, and hypnagogic hallucinations can be attributed to REM sleep disturbances.[43]

Loss of normal function of the hypocretin-orexin neurotransmitter system plays a central role in the pathophysiology of narcolepsy. Neurons containing hypocretin-orexin are found in the lateral hypothalamus and project to various parts of the brain that are thought to regulate sleep. In 75% of patients with narcolepsy, hypocretin-orexin is undetectable in cerebrospinal fluid.[44,45] Since patients with narcolepsy and cataplexy have low concentrations of hypocretin-1 (less than 110 pg/mL [ng/L; 31 pmol/L]),[9] an autoimmune process may be responsible for the destruction of hypocretin-producing cells.[46,47] Molecular studies of human leukocyte antigens (HLA) have found a high prevalence of the HLA-DR2 and HLA-DQ6/DQB1 haplotypes in patients with narcolepsy.[48] However, the HLA-DR2 haplotype is also common in the non-narcolepsy populations and is not diagnostic.[47] As 3% of patients have a first-degree relative with the disorder, there may also be a genetic component associated with this disease.[44] Lastly, as the onset of this disease occurs in adolescence or adulthood, but not at birth, environmental influences also play a role.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Narcolepsy

Symptoms

- Patients may complain of EDS and disrupted nighttime sleep; often they have some accompanying REM sleep abnormality, sleep paralysis, cataplexy, and/or hallucinations.

Laboratory Tests

- Although not routinely tested, there is a high incidence of human leukocyte antigen (HLA) haplotypes DR2 and HLA-DQ6/DQB1 in narcolepsy.
- Cerebrospinal fluid (CSF) concentrations of hypocretin-1 can be measured to confirm a diagnosis. CSF concentrations less than 110 pg/mL (ng/L; 31 pmol/L) positively predict narcolepsy.

Other Diagnostic Tests

- Narcolepsy is diagnosed using the multiple sleep latency test (nap test). The patient takes four to five naps in a day, and narcolepsy is diagnosed if the patient falls asleep quickly, within less than 5 minutes, and goes into REM sleep in two of those nap periods.

TREATMENT

Desired Outcomes

Nonpharmacologic management of narcolepsy includes counseling the patient and family concerning the illness to alleviate misconceptions around the individual's behavior. Good sleep hygiene should be encouraged, as well as two or more scheduled daytime naps as naps lasting 15 minutes each can help the individual with narcolepsy feel refreshed. The primary objective of pharmacologic treatment of narcolepsy is to reduce symptoms that adversely influence the patient's quality of life and to produce the fullest possible return of normal function for individuals within work, school, home, and social settings.

Pharmacologic Therapy

7 Pharmacologic management of narcolepsy is focused on two primary areas: treatment of EDS and REM sleep abnormalities. Clinical practice guidelines for treatment of narcolepsy in adults were updated and strongly recommend modafinil, pitolisant, sodium oxybate, and solriamfetol for the treatment of narcolepsy. Armodafinil, dextroamphetamine, and methylphenidate are also suggested as second-line options. Medication therapy for narcolepsy is summarized in Table 92-4.

TABLE 92-4

Dosing of Medications Used to Treat Narcolepsy

Generic Name	Brand Name	Initial Dose (mg)	Usual Dose (mg)	Comments
Excessive daytime somnolence				
Dextroamphetamine	Dexedrine	5-10	5-60	Concurrent use of amphetamines and acidic foods may reduce amphetamine absorption
Dextroamphetamine/Amphetamine salts[a]	Adderall	5-20	5-60	See above
Methamphetamine[b]	Desoxyn	5-15	5-15	See above
Lisdexamfetamine	Vyvanse	20-30	20-70	Prodrug of dextroamphetamine
Methylphenidate	Ritalin	10-40	30-80	May increase risk of bleeding with concomitant warfarin therapy
Solriamfetol	Sunosi	75	75-150	Renally eliminated; specific dosing required for renal impairment
Modafinil	Provigil	100-200	200-400	May reduce effectiveness of hormonal contraceptives
Armodafinil	Nuvigil	150	150-250	May reduce effectiveness of hormonal contraceptives
Sodium oxybate[c]	Xyrem	4.5 g/night	4.5-9 g/night	Do not use with other CNS depressants
Pitolisant[c]	Wakix	8.9	17.8-35.6	May reduce effectiveness of hormonal contraceptives
Agents for cataplexy				
Atomoxetine	Strattera	18-100	40-100	Lower doses in CYP2D6 poor metabolizers
Fluoxetine	Prozac	10-20	20-80	Will see cataplexy benefits sooner than antidepressant benefits
Imipramine	Tofranil	50-100	50-250	Anticholinergic adverse effects
Nortriptyline	Aventyl, Pamelor	50-100	50-200	Anticholinergic adverse effects
Protriptyline	Vivactil	5-10	5-30	
Venlafaxine	Effexor	37.5	37.5-225	May increase blood pressure
Selegiline	Eldepryl	5-10	20-40	Doses less than 10 mg/day do not require dietary tyramine restrictions

[a] Dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine aspartate, and amphetamine sulfate.

[b] Not available in some states.

[c]Also is effective in treating cataplexy.

Data from References 47,49.

Modafinil, a racemic compound unrelated to psychostimulants, and armodafinil (its active R-isomer) are FDA-approved for treatment of EDS in narcolepsy. The precise mechanism of action of modafinil and armodafinil is not fully understood. Common adverse reactions are usually mild and include headache, nausea, nervousness, anxiety, and insomnia. The dose of modafinil is between 100 and 400 mg/day, and armodafinil doses are between 150 and 250 mg/day.[50] Although both of these agents are effective in treating EDS, they lack efficacy for the treatment of cataplectic symptoms.[51]

EDS can also be treated with stimulants to improve alertness and to increase daytime performance. Dextroamphetamine and methylphenidate also have FDA approval for the treatment of narcolepsy. Methamphetamine and mixed amphetamine salts have also been used on an off-label basis. Methylphenidate and amphetamines have a fast onset of action and durations of 6 to 10 and 3 to 4 hours, respectively. The doses of methylphenidate and amphetamine formulations can range from 5 to 60 mg daily.

Stimulants improve alertness and daytime performance, and they can elevate mood and prevent sleep. Adverse medication reactions can include insomnia, hypertension, palpitations, and irritability. Tolerance to long-term stimulant therapy can occur, necessitating dosage increases. Amphetamine use is associated with a greater likelihood of a substance use disorder and tolerance, especially when prescribed in high doses. Lisdexamfetamine is an amphetamine prodrug rapidly absorbed and converted in the body to dextroamphetamine, which has a longer duration of action and less risk of a substance use disorder since it is active only when taken orally.

To individualize treatment of narcolepsy many clinicians prescribe both immediate-release and sustained-release stimulants to increase alertness throughout the day. Sustained-release stimulants are prescribed with scheduled administration times, and immediate-release stimulants can be taken as needed when the patient requires alertness (eg, driving). There are no guidelines that recommend pharmacogenomics testing to predict response to simulant medication when being used for the treatment of sleep disorders.

Solriamfetol, a norepinephrine and dopamine reuptake inhibitor, and pitolisant, a histamine-3 antagonist/inverse agonist, are relatively new medications approved for treatment of EDS in narcolepsy. Pitolisant is also approved for treatment of cataplexy, and because it has a completely different mechanism of action, it may be prescribed with other wake-promoting medications. Solriamfetol improves wakefulness and quality of life in patients with narcolepsy.[49]

The most commonly used treatments for cataplexy are tricyclic antidepressants (TCAs), selective norepinephrine reuptake inhibitors (SNRIs), and selective serotonin reuptake inhibitors (SSRIs). The mechanism of antidepressants in relieving cataplexy, hypnagogic hallucinations, and sleep paralysis is thought to be mediated through blockade of serotonin and norepinephrine reuptake in the locus coeruleus and raphe which subsequently suppresses REM sleep.[52] Imipramine, protriptyline, clomipramine, fluoxetine, and nortriptyline are effective in approximately 80% of patients. Selegiline improves hypersomnolence and cataplexy through REM suppression and an increase in REM latency. Atomoxetine may improve cataplexy and sleepiness in children, but is less effective than other therapies in older teenagers and adults. In contrast to the antidepressants, methylphenidate and amphetamines alone are usually ineffective for complete relief from cataplexy.

Sodium oxybate (γ-hydroxybutyrate, Xyrem) improves symptoms of EDS and decreases episodes of sleep paralysis, cataplexy, and hypnagogic hallucinations. A low sodium formulation (Xywav) was developed and has similar dosing to the traditional formulation. Nightly administration of sodium oxybate changes sleep architecture to resemble normal sleep. It increases slow-wave sleep, decreases nighttime awakenings, and increases REM efficiency.[53] Sodium oxybate is available only as a liquid and is taken in two doses; one is taken at bedtime and the second dose is taken 2.5 to 4 hours later. Sodium oxybate is a potent sedative-hypnotic and should not be used concomitantly with any other sedating medications. The most common adverse reactions include nausea, somnolence, confusion, dizziness, and incontinence.

Evaluation of Therapeutic Outcomes

Patients with narcolepsy should keep a diary of the frequency and severity of cataplexy, sleep paralysis, and sleep hallucinations. Patients should be evaluated regularly during medication titrations and then every 6 to 12 months to assess for adverse medication reactions (eg, sleep disturbances, hypertension, and cardiovascular abnormalities). The healthcare provider should consider the benefit-to-risk ratio for the individual patient, the cost of medication, the convenience of administration, and the cost of laboratory tests when selecting narcolepsy therapies.[49] One wake-promoting agent may work better than another in an individual patient. Thus, if one agent is not effective at adequate doses, a trial with another agent should be undertaken.

CIRCADIAN RHYTHM DISORDERS

The sleep–wake cycle is under the circadian control of oscillators and can be disrupted by misalignment between an individual's biologic clock and external demands on the sleep cycle. Circadian rhythm sleep disorders usually present with either insomnia or hypersomnia, depending on the individual's performance requirements. Two commonly occurring circadian rhythm sleep disorders are jet lag and shift work sleep problems.

Jet Lag

Jet lag occurs when a person travels across time zones, and the external environmental time is mismatched with the internal circadian clock. Disturbances in sleep due to jet lag typically last for 2 to 3 days, but can last as long as 7 to 10 days if the time zone changes are greater than 8 hours. Compared with westward travel, eastward travel is associated with a longer duration of jet lag. In addition to decrease in alertness and performance, jet lag can also lead to increased incidence of gastrointestinal disturbances.

⑧ Treatment of jet lag includes nonpharmacologic approaches alone or in combination with medication therapy. Jet lag can be minimized in coast-to-coast travel in the United States if the duration is less than 7 days and the normal sleep–wake cycle is observed. For travel lasting longer than 7 days, jet lag severity can be lessened by 1- to 2-hour adjustments in sleep and wake times prior to departure to the destination time zone. Appropriate timing of light exposure along with short-acting BZDRAs, ramelteon, and 0.5 to 5 mg melatonin, taken at appropriate target bedtimes for east or west travel, reduce jet lag and shorten sleep latency.[54]

Shift Work Sleep Disorder

Shift workers comprise approximately 20% of the workforce.[55] Night shift work causes a misalignment in the sleep–wake cycle and circadian rhythm that is associated with a decrease in alertness, performance, and quality of daytime sleep. More than 65% of workers on rotating shifts complain of insomnia, compared with only 20% who work one shift.[56] Shift workers ultimately are at risk of developing shift work sleep disorder, which is a complaint of insomnia or excessive sleepiness that occurs because of circadian sleep disruption due to working shifts during normal sleep time.[9,55] Shift workers have a higher injury rate, divorce rate, occurrence of on-the-job sleepiness, and incidence of substance use disorder. They may also be at increased risk of developing peptic ulcers, depression, breast cancer, and sleepiness-related accidents.[55–57] Night shift workers are usually in a state of permanent circadian misalignment because of the tendency to revert to conventional sleep schedules on nonwork days.[56]

Treatment for shift work sleep problems includes optimizing sleep hygiene, extending daytime sleep by sleeping in the afternoon, scheduling a 2- to 3-hour nap on days off from work, or switching to a day shift job. Short-acting BZDRAs, ramelteon, and melatonin can consolidate sleep during day sleep periods and reduce lost sleep time. Modafinil and armodafinil are FDA-approved to improve wakefulness in patients with EDS associated with shift work sleep disorder. Scheduled exposure to bright lights at night and darkness in the daytime improves adaptation to night work and daytime sleep.[56]

Restless Legs Syndrome

RLS, or Willis-Ekbom syndrome, is characterized by paresthesias that are usually felt deep in the calf muscles resulting in the urge to keep limbs in motion. Additionally, these paresthesias can also appear in the thighs and arms. RLS occurs in both sexes, and it occurs more frequently in older individuals. It has been associated with chronic kidney disease and pregnancy. Additionally, RLS can be caused by iron deficiency in the substantia nigra in the CNS[58] and caffeine, stress, alcohol, and fatigue can worsen symptoms. The diagnosis of RLS is based on patient- or partner-reported symptoms and specific diagnostic criteria that include (a) an urge to move the limbs that are usually associated with uncomfortable and unpleasant sensations, (b) symptoms that begin or worsen during rest or inactivity, (c) symptoms that are exclusively present or worse in the evening or night, (d) symptoms that are temporarily relieved by movement, and (e) occurrence of symptoms is not accounted for as symptoms of another medical condition.[59] The discomfort returns when the person tries to sleep, resulting in insomnia. RLS adversely affects work performance, quality of life, and increased risk for cardiovascular disease.[60–62]

Periodic Limb Movements of Sleep

Periodic limb movements of sleep (PLMS) are stereotypic, repetitive, periodic movements of the legs that occur during sleep every 20 to 40 seconds and last 10 minutes to several hours.[66] The movements usually involve the big toe, but the ankle, knee, and hip can also flex. They can be terminated by a violent kick or other body movements. Often patients will be unaware of these movements and only recognize consequent insufficient sleep and morning leg cramps. A bed partner can describe PLMS. PLMS is diagnosed in the sleep laboratory using electromyogram recordings.

PLMS can occur with RLS or alone because of systemic disease (eg, renal failure) or medication therapy.[72] In fact RLS patients commonly have PLMS, while approximately one-third of patients with PLMS have RLS.[66] TCAs, SSRIs, dopaminergic antagonists, xanthines, nicotine, alcohol, and caffeine can all worsen PLMS.

TREATMENT

Pharmacologic Therapy

For treatment of intermittent symptoms, occurring less than 2 days per week, levodopa or benzodiazepines are recommended for as-needed use. However, for chronic, persistent symptoms, alternative therapies are recommended.

⑨The alpha-2-delta ligands gabapentin, gabapentin enacarbil, and pregabalin are standard therapy for chronic RLS and have not caused symptom augmentation during chronic therapy. Gabapentin 100 to 1800 mg near bedtime may be especially effective for those with paresthetic or painful RLS symptoms.[63] Gabapentin enacarbil (Horizant) is a gabapentin prodrug that is FDA-approved for the treatment of RLS at a dose of 300 to 600 mg taken at 5 pm. Pregabalin has similar or greater efficacy for RLS compared to dopamine agonists. These medications should have the dose slowly increased to achieve therapeutic effect, as their benefit may not be evident until therapeutic doses are reached. Iron studies should be completed in patients with RLS and iron supplementation initiated in those who are deficient. In patients with ferritin concentrations less than 75 mcg/L (ng/mL) or transferrin saturation less than 20%, iron supplementation improves RLS symptoms.[64,65]

The dopamine agonists ropinirole, pramipexole, and rotigotine are FDA-approved for RLS treatment.[66] Lower doses of dopamine agonists are used when treating RLS compared with Parkinson’s disease. Providers should caution patients that compulsive behaviors (eg, gambling, shopping, eating, and so on) and sudden periods of extreme sleepiness may emerge during therapy with dopamine agonists. Due to levodopa’s short half-life, it may not provide relief over the entire night. Additionally, dopaminergic agents are associated with a high incidence of symptom augmentation, which is a worsening in symptom severity, increase in symptom distribution, emergence of symptoms earlier in the evening, shortening duration of symptom control, and need for escalating dopaminergic doses to control symptoms. Augmentation can be treated by tapering and discontinuing dopaminergic medications, repleting low body iron stores and switching to alternative medications such as gabapentin. Sedative-hypnotic agents can be effective in patients who have frequent awakenings from their RLS symptoms. Clonazepam at doses ranging from 0.5 to 2 mg has been most frequently studied; however, patients may experience carryover sedation because of its long duration of action. Shorter half-life sedative-hypnotics (eg, zolpidem, zaleplon) can improve sleep and reduce daytime sleepiness without carryover sedation. Opioids such as methadone 5 to 20 mg, and prolonged release oxycodone-naloxone are effective in patients with painful RLS; however, the potential for tolerance and physical dependence on opioid therapy should be considered. Patients with RLS or PLMS should be evaluated regularly to monitor for excessive daytime somnolence, tolerance, efficacy, and adverse effects of the medication. Therapy should be monitored for adverse medication reactions found in Table 92-5.

TABLE 92-5

Monitoring Patients Taking Medications for RLS and PLMS

Medication or Medication Class	Adverse Medication Reaction	Monitoring Parameter	Comments
Dopamine agonists	Compulsive behaviors	Frequency and quantity of eating, gambling, shopping, other reward behaviors	May occur at any time during therapy but is dose-related
Levodopa/Carbidopa	Symptom augmentation	Location and timing of RLS symptoms	Appearance of symptoms in other areas of body and earlier in day
Gabapentin/Pregabalin	Dizziness	Subjective dizziness, falls	–
Sedative-hypnotics (eg, clonazepam, temazepam, zolpidem, and so on)	Carryover sedation	Morning sleepiness, grogginess	More likely to occur with longer duration agents
Opioids (eg, oxycodone, codeine, hydrocodone, and so on)	Tolerance, constipation	Patient RLS symptoms and response to ongoing therapy	–
Oral iron therapy (eg, ferrous sulfate, and so on)	Gastrointestinal upset, constipation	Monitor for constipation	Prophylactic stool softeners may be necessary to reduce risk of constipation

The treatment approach for PLMS is similar to that of RLS in that if the PLMS do not cause disruptions for the patient or bed partner or daytime symptoms, they may not require treatment. Symptomatic or problematic PLMS should be treated with dopaminergic medications or alpha-2-delta ligands to suppress limb movements or sedative-hypnotics to reduce awakenings and consolidate sleep.

PARASOMNIAS

Parasomnias are abnormal behavior or physiologic events that either occur during sleep or are exaggerated by sleep. Many of these disorders are considered to be disorders of partial arousal from various sleep stages. Parasomnias can be categorized as disorders of arousal (sleepwalking, sleep terrors), sleep–wake transition disorders (sleep-talking), rhythmic movement disorder, REM parasomnias (REM behavior disorder, nightmares), and miscellaneous parasomnias (enuresis, bruxism). Sleepwalking, sleep terrors, and sleep-talking predominantly occur during NREM sleep, whereas others, such as REM behavior disorder, occur during REM sleep.

Sleepwalking and sleep terrors are found normally in children between the ages of 4 and 12 years and usually resolve in adolescence. These disorders are increasingly recognized to also occur in adulthood, and, contrary to previous beliefs, are not related to psychological or psychiatric pathology.[67] In adults, sleep terrors can begin between the ages of 20 and 30 years. Onset of sleepwalking in adults without a childhood history of sleepwalking should prompt a search for a neurologic or substance use disorder.[68] Sleepwalking and sleep terror disorder involve intrusions of wakefulness into NREM sleep during the first third of the night. In sleepwalking, individuals become ambulatory, are difficult to awaken, and are amnestic for the event. Sleep terrors involve intense fear and autonomic arousal. Individuals are difficult to awaken, inconsolable, and amnestic for the event.[68] Patients with REM behavior disorder act out their dreams, often in a violent manner, and are at risk for injury.

Treatment of sleepwalking involves protecting the individual from harm by putting safety latches on doors and windows, removing hazardous objects from bedrooms, and covering glass doors with heavy curtains. In adult patients, benzodiazepines, SSRIs, or TCAs can be beneficial therapies for sleepwalking or other NREM disorders of arousal.[67] Benzodiazepines can also be helpful in curtailing sleep terrors in adults.[68] Nightmares are anxiety-provoking dreams characterized by vivid recall and treatment is directed at reducing stress, anxiety, and sleep deprivation. In extreme cases, low-dose benzodiazepines can be indicated. Clonazepam is the treatment of choice for REM behavior disorder. Melatonin (3-12 mg at bedtime) and pramipexole can also be an effective therapy for REM behavior disorder.[69]

CONCLUSION

Sleep and wake disorders are common but they may be challenging to diagnose since clinical presentation and precise symptoms may be unknown to the individual who is asleep. Practitioners need to perform a sleep history that involves both the patient and their bedpartner. Treatments for sleep and wake disorders are effective, but not curative, and need to be monitored carefully for both safety and efficacy. Practitioners should use the lowest doses of medications for the shortest durations possible, and thoroughly investigate potential underlying causes for sleep and wake disturbances.

ABBREVIATIONS

AutoPAP	auto-titrating positive airway pressure
BZDRA	benzodiazepine receptor agonist
CNS	central nervous system
CPAP	continuous positive airway pressure
CSA	central sleep apnea
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*
DORA	Dual orexin receptor antagonist
EDS	excessive daytime sleepiness
GABA	γ-aminobutyric acid
GI	gastrointestinal
HLA	human leukocyte antigen
NREM	nonrapid eye movement
OSA	obstructive sleep apnea
PAP	positive airway pressure
PLMS	periodic limb movements of sleep
PSG	polysomnography
RDI	respiratory disturbance index
REM	rapid eye movement
RLS	restless legs syndrome
SSRI	selective serotonin reuptake inhibitor
TCA	tricyclic antidepressant

SELF-ASSESSMENT QUESTIONS

1. SB is a 28-year-old who complains that they had difficulty sleeping over the last several weeks and that it is beginning to interfere with work. They state that they had been working long hours and feeling stressed, so they participate in aerobics before bed around 10 pm. What would you recommend initially to SB?

A. Trazodone

B. Flurazepam

C. Zolpidem

D. Sleep Hygiene

2. A 35-year-old individual, complains of difficulty with sleep onset for more than 12 weeks. They have appropriately tried sleep-hygiene therapy, but that has not worked. The plan is to initiate medication therapy. If the patient has no contraindications, and no medical causes for these sleep difficulties, which of the following therapies would be best for initial therapy?

A. Amitriptyline

B. Fluoxetine

C. Doxepin

D. Zolpidem

3. A 42-year-old individual who recently lost their partner tells you that they are not sleeping at night. After further questioning, you determine that they do not have depression or a substance use disorder. What would you recommend?

A. Educate concerning sleep hygiene.

B. Recommend a trial of a short-acting BZDRA.

C. Recommend a trial of fluoxetine.

D. Recommend a trial of amitriptyline.

4. A 27-year-old individual has trouble due to waking up in the middle of the night. Which of the following is *least* likely to be effective if taken at bedtime?

A. Zaleplon

B. Temazepam

C. Zolpidem CR

D. Estazolam

5. What is the best way to avoid tolerance and misuse in this patient?

A. Use high-dose BZDRA therapy for as long as possible.

B. Use high-dose BZDRA therapy for as short a time as possible.

C. Use low-dose BZDRA therapy for as long as possible.

D. Use low-dose BZDRA therapy for as short a time as possible.

6. A 28-year-old individual has a chief complaint of insomnia occurring for the last 5 months. They just graduated from pharmacy school and spends the evening worrying if they made a mistake during their busy days at work. All other mental health and medical conditions have been ruled out. How would you approach treating this patient?

A. Recommend a short-term trial of lorazepam.

B. Recommend a short-term trial of clonazepam.

C. Recommend an approach that would include education concerning good sleep. hygiene, supportive therapy, and trazodone as an adjunct if needed.

D. Recommend cognitive therapy alone.

7. A 34-year-old individual begins working overnight shifts. They find difficulty sleeping during daytime hours. What is the best recommendation you can provide to help with this complaint?

A. Drink alcohol after their work shift to help with falling asleep.

B. Take melatonin, ramelteon, or a short-acting BZDRA at bedtime.

C. Take an SSRI after work to help falling asleep.

D. Take modafinil prior to going to work to help staying awake overnight.

8. A 54-year-old patient has been having difficulty maintaining sleep. They sleep fine until around 1 am when they wake up and they would like to sleep until 6:30 am. Which of the following would be the most appropriate?

A. Diazepam 5 mg PO at bedtime

B. Eszopiclone 3 mg PO when awakening at 1 am

C. Zolpidem 3.5 mg SL when he awakening at 1 am

D. Flurazepam 30 mg PO at bedtime

9. A 46-year-old with chronic obstructive pulmonary disease has difficulty falling asleep. Which pharmacologic agent would you recommend in this patient?

A. Temazepam

B. Amitriptyline

C. Ramelteon

D. Levothyroxine

10. DB is a 58-year-old individual with obstructive sleep apnea and daytime sleepiness but no other medical conditions. What is the best therapy for this patient?

A. Solriamfetol

B. Uvulopalatopharyngoplasty

C. Oral appliances

D. Positive airway pressure

11. Sleep apnea can lead to all of the following sequelae *except*?

A. Depression

B. Stroke

C. Hypertension

D. Jet lag

12. Which of the following has a strong recommendation for the treatment of daytime sleepiness associated with narcolepsy according to recent clinical practice guidelines?

A. Methamphetamine

B. Modafinil

C. Zolpidem

D. Imipramine

13. Which of the following is an effective treatment for cataplexy associated with narcolepsy?

A. Methamphetamine

B. Medroxyprogesterone acetate

C. Modafinil

D. Pitolisant

14. It is believed that restless legs syndrome results from:

A. Hypocretin-orexin neuron dysfunction in the hypothalamus

B. Repetitive airway closure during sleep

C. Iron deficiency in the substantia nigra of the CNS

D. Loss of serotonin receptors in the dorsal raphe nucleus

15. Which of the following would be the correct recommendation for a patient with internet addiction disorder and restless legs syndrome who has RLS?

A. Gabapentin

B. Doxepin

C. Ropinirole

D. Pramipexole

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** They should improve sleep hygiene (exercise before bed) before trying medications. For some people, exercising immediately prior to bedtime activates the sympathetic nervous system and produces difficulty with sleep. See Nonpharmacologic Therapy of Insomnia Section.

2. **D.** Zolpidem is indicated for difficulty with sleep onset and is preferred first-line therapy. See subsection “Benzodiazepine Receptor Agonists” under “Pharmacologic Therapy” of the section “Insomnia.“

3. **B.** BZDRAs are first-line therapies for short-term treatment of insomnia and in this case a trial of a short-acting BZDRA is indicated. See Fig. 92-1.

4. **A.** Zaleplon has a short duration of action and will not last through the night to prevent middle-of-the-night awakenings if it is taken at bedtime. See subsection “Benzodiazepine Receptor Agonists” under “Pharmacologic Therapy” of the section “Insomnia.“

5. **D.** By using the lowest dose BZDRA for the shortest duration you can minimize the risk of tolerance or a substance use disorder. Higher doses and longer durations of treatment will increase these risks. See subsection “Benzodiazepine Receptor Agonists” under “Pharmacologic Therapy” of the section “Insomnia.“

6. **C.** A comprehensive approach to sleep hygiene, including supportive therapy, is indicated for this patient to determine the causes of sleep problems. Trazodone may be provided medication therapy if indicated. See the subsection “Sedating Antidepressants” of “Nonpharmacologic Therapy” and “Pharmacologic Therapy” of the section “Insomnia.”

7. **B.** Melatonin, ramelteon, or short-acting BZDRA are effective in helping initiate sleep in patients with shift work sleep disorder. See “Circadian Rhythm Disorders” section.

8. **C.** Zolpidem sublingual indicated for middle-of-the-night awakenings. See subsection “Benzodiazepine Receptor Agonists” under “Pharmacologic Therapy” of the section “Insomnia.“

9. **C.** Ramelteon is safe and effective in patients with COPD. See “Melatonin Agonist” section under “Pharmacologic Therapy” of the section “Insomnia.“

10. **E.** CPAP is first-line therapy for OSA with sleepiness. CPAP is noninvasive, effective, and is universally prescribed as first therapy for OSA. See “Nonpharmacologic Therapy” section under “Sleep Apnea.“

11. **D.** Sleep apnea is not associated with development of Jet Lag. Sleep apnea is associated with development of hypertension, risk of stroke, and depression. See “Sleep Apnea” section.

12. **B.** Modafinil is recommended (strong) for treatment of daytime sleepiness with narcolepsy. See “Pharmacologic Therapy” section of “Narcolepsy.“

13. **D.** Pitolisant is indicated for cataplexy with narcolepsy. See “Pharmacologic Therapy” section of “Narcolepsy.“

14. **C.** Localized CNS iron deficiency has been documented in the cadaver studies of brains of individuals who had RLS and iron deficiency exacerbates and, in some cases, initiates RLS symptoms. See “Restless Legs Syndrome” section.

15. **A.** Gabapentin will not increase risk of impulse control disorders and is first-line therapy for RLS. Dopamine agonists are not the best choice in this patient since they are associated with the development of impulse control disorders which may be particularly problematic in patients with a substance use disorder or other use disorder. See “Pharmacologic Therapy” of the “Restless Legs Syndrome” section.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 94: Diabetes Mellitus

Jennifer Trujillo; Stuart Haines

KEY CONCEPTS

KEY CONCEPTS

① Diabetes mellitus (DM) is a metabolic disorder. While there are numerous etiological causes, defects in insulin secretion, insulin action (sensitivity), or both lead to elevations in blood glucose as well as altered fat and protein metabolism.

② DM is a leading cause of eye and kidney disease. Patients with DM are at high risk for CV events, heart failure, and atherosclerotic disease.

③ The two most common classifications of DM are type 1 (absolute insulin deficiency) and type 2 (relative insulin deficiency due to β-cell dysfunction coupled with insulin resistance). They differ in clinical presentation, pathophysiology, and treatment approach.

④ The prevalence of type 2 DM has doubled worldwide over the last 40 years. This has been attributed to an alarming increase in the prevalence of obesity due to diminished physical activity and increased caloric consumption.

⑤ The diagnosis of diabetes is made using any of the following criteria: (1) fasting plasma glucose (FPG) ≥126 mg/dL (7.0 mmol/L); (2) a hemoglobin A1C (A1C) ≥6.5% (0.065; 48 mmol/mol); (3) a random plasma glucose level ≥ 200 mg/dL (11.1 mmol/L) coupled with classic symptoms of diabetes; or (4) a 2-hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L) during a 75-g oral glucose tolerance test (OGTT). A diagnosis using criteria 1-3 requires two abnormal test results from the same sample or in two separate test samples.

⑥ The goals of therapy in DM are to achieve optimal glycemic control (based on age, comorbid conditions, and patient preferences), reduce the onset and progression of diabetes-related complications, aggressively address CV risk factors, and improve quality of life.

⑦ Intensive glycemic control prevents the onset and slows the progression of microvascular complications (eg, neuropathy, retinopathy, and nephropathy).

⑧ Knowledge of the patient's meal patterns and activity levels, as well as the pharmacologic properties of antihyperglycemic agents, is essential to creating an individualized treatment plan that achieves optimal glycemic control, avoids hypoglycemia, and minimizes adverse effects.

⑨ Metformin is the drug of choice and, in the absence of contraindications or intolerability, should be included in the treatment regimen for most patients with type 2 DM due to its effectiveness, low risk of hypoglycemia, positive or neutral effects on weight, potential positive impact on CV risk, and low cost.

⑩ Type 2 DM often requires the use of multiple therapeutic agents (combination therapy) including oral and injected antihyperglycemics to achieve and maintain optimal glycemic control. A persistent decline in β-cell function over time often necessitates periodic adjustment and changes in therapy.

⑪ Insulin therapy is required in type 1 DM. Intensive basal-bolus insulin therapy, either via multiple daily injections of insulin or continuous subcutaneous insulin infusion therapy (aka an insulin pump), in motivated individuals is more likely to achieve optimal glycemic control. Basal-bolus therapy includes a long-acting insulin to address fasting glucose and a rapid-acting insulin for mealtime coverage. The use of adjunctive therapy in combination with insulin in patients with uncontrolled or erratic glucose concentrations may be warranted.

⑫ Aggressive management of CV risk factors in DM is necessary to reduce the incidence of CV events and death. This includes smoking cessation, use of moderate or high potency statins in most patients with DM, and treatment of hypertension.

⑬ Good blood pressure control in patients with diabetes lowers not only the risk of retinopathy and nephropathy but also CV events.

⑭ Strategies to prevent type 1 DM have not yet been successful. For patients at high risk, type 2 DM can be delayed or prevented by engaging in regular aerobic exercise, losing weight, reducing dietary fat, and increasing fiber intake. These lifestyle habits can reduce the risk of type 2 DM by 60%. Although no medication is currently FDA approved to prevent diabetes, several have been shown to delay diabetes onset in high-risk patients.

⑮ Repeated inaction by practitioners to intensify treatment when patients are not meeting treatment goals is called therapeutic inertia. Several factors contribute to therapeutic inertia. This is a common problem and among the leading contributors to poor outcomes. Diabetes is a chronic condition that requires periodic medication changes to attain and maintain glycemic goals.

⑯ Patient self-management, therapeutic lifestyle behaviors, and appropriate medication use are equally important components of each patient's treatment plan. Interprofessional teams including physicians (primary care, endocrinologists, ophthalmologists), dentists, dietitians, nurses, pharmacists, podiatrists, social workers, behavioral health specialists, and certified diabetes care and education specialists (CDCESs) working together can assist persons with DM in achieving optimal health outcomes.

BEYOND THE BOOK

BEYOND THE BOOK

Part 1:

Donna is a 53-year-old woman with a 5-year history of type 2 DM. She also has dyslipidemia and hypertension. She has atherosclerotic cardiovascular disease with two coronary artery stents placed 1 year ago. She has gained 5 lb (2.3 kg) in the last 6 months. She takes metformin 1,000 mg by mouth twice daily for type 2 DM. Her most recent laboratory results include: A1C 8.1% (0.081; 65 mmol/mol), eGFR > 60 mL/min/1.73 m^2, UACR 14 mg/g (1.6 mg/mmol) . She wants to lose weight and has commercial insurance. The patient's nurse practitioner wrote a prescription for insulin glargine U-100 10 units SC once daily.

Find the current diabetes treatment guidelines from both the American Diabetes Association (ADA) and the American Association of Clinical Endocrinologists/American College of Endocrinology (AACE/ACE). Is this treatment approach in Donna's case consistent with the guidelines? If it is, explain why? If it is not, determine what would be recommended instead and explain why?

Part 2:

Assume that the prescription for insulin glargine is appropriate. Review the following resource on *how to inject insulin*.

Find two additional resources that you could use when educating Donna on this new prescription. How did you find them? How did you determine the resource was from a reputable and reliable source? What are the key components you should discuss with this patient about the proper use of insulin?

INTRODUCTION

① ② Diabetes mellitus (DM) is a diverse group of metabolic disorders that all have chronically elevated blood glucose (BG) as their defining feature.

In addition to hyperglycemia, DM is associated with abnormal fat and protein metabolism. In the absence of effective treatment, DM can lead to acute complications such as diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic syndrome (HHS). Chronic hyperglycemia can cause vascular and nerve damage, resulting in microvascular, macrovascular, and neuropathic complications. DM is a worldwide problem, significantly impacting people and healthcare systems in low-, middle-, and high-income countries.[1] More than 442 million adults around the globe are now living with DM, and its prevalence has nearly doubled over the last 30 years. According to the Centers for Disease Control and Prevention, slightly more than 34 million Americans, including 13% of adults, have DM.[2] While 1.5 million new cases of DM are diagnosed in the United States every year, one in four Americans with DM are unaware they have it. While these numbers are startling, the number of adults with prediabetes is far greater—an estimated 88 million in the United States alone. Prediabetes is a condition of abnormal BG that is not sufficiently high to meet the thresholds that define diabetes but often progresses to the diagnosis. The total direct and indirect medical costs for treating people with DM in the United States were $327 billion in 2017.[3] The average person with DM spent $16,750 in 2017 on medical care, an amount that was nearly two-and-half times greater than the amount spent by people without DM. DM is the seventh leading cause of death in the United States and among the principal causes of end-stage kidney disease (ESKD), lower extremity amputations, and blindness. Finally, people with DM are at far greater risk for CV disease (eg, myocardial infarction, ischemic stroke).[2] Optimal management of DM substantially lowers the risk of complications, increases life expectancy, and improves the quality of life.

EPIDEMIOLOGY

③ The vast majority of patients with DM are classified into one of two broad categories: type 1 DM and type 2 DM.[4] Patients with type 1 DM have an absolute insulin deficiency. Patients with type 2 DM have varying degrees of β-cell dysfunction often coupled with insulin resistance. Women who develop diabetes during pregnancy are classified as having gestational diabetes (GDM). Less common types of diabetes are caused by genetic defects, pancreatic destruction, endocrine disorders, and medications. See Table 94-1.

TABLE 94-1

Classification of Diabetes Mellitus

Type 1 diabetes[a] (immunologically mediated destruction of β-cells leading to absolute insulin deficiency)
Type 2 diabetes (progressive loss of β-cell insulin secretory function accompanied by resistance to insulin action)
Gestational diabetes mellitus
Monogenic defects
Maturity-onset diabetes of the young (MODY) caused by a mutation in GCK, HNF1A, HNF1B, or HNF4A gene
Neonatal diabetes caused by a mutation in KCNJ11, ABCC8, INS, GATA6, EIF2AK3, or FOXP3 gene
Genetic syndromes associated with diabetes
Down syndrome
Hemochromatosis
Klinefelter syndrome
Turner syndrome

Diseases impacting the pancreas leading to diabetes
Cystic fibrosis
Pancreatitis
Pancreatic cancer
Pancreatectomy
Posttransplantation diabetes mellitus
Endocrine diseases frequently associated with diabetes
Acromegaly
Aldosteronoma
Cushing syndrome
Glucagonoma
Hyperthyroidism
Pheochromocytoma
Somatostatinoma
Medication-induced hyperglycemia[5]
Atypical antipsychotics (eg, risperidone, olanzapine)
β-blockers (eg, propranolol, atenolol)
β-adrenergic agonists (eg, albuterol)
Calcineurin inhibitors (eg, cyclosporine, tacrolimus)
Diazoxide
Gatifloxacin

Glucocorticoids (eg, dexamethasone, prednisone)
Growth hormone (rhGH)
HMG-CoA reductase inhibitors (eg, atorvastatin, simvastatin)
Niacin/nicotinic acid
Pentamidine
Protease inhibitors (eg, ritonavir, saquinavir)
Thiazide diuretics (eg, chlorthalidone, hydrochlorothiazide)

[a] Patients with any form of diabetes may require insulin treatment at some stage of their disease. Insulin use does not itself classify the type of diabetes.

Data from Reference 4.

Type 1 DM accounts for 5% to 10% of all cases of DM and is most often due to autoimmune destruction of the pancreatic β-cells.[6] The prevalence of β-cell autoimmunity in a population is directly related to the incidence of type 1 DM. For example, in Sweden and Finland 3% to 4.5% of the population have circulating islet cell autoantibodies (ICAs), and this is associated with the highest incidence of type 1 DM in the world: 22 to 35 per 100,000 people. The worldwide prevalence of type 1 DM is increasing, but the cause is not fully understood.[7]

Markers of β-cell autoimmunity can be found in many adults with diabetes.[6] A variant of type 1 DM is called latent autoimmune diabetes of adults (LADA). These patients often have a poor response to oral agents and require insulin therapy much sooner than most patients with type 2 DM. The cause of idiopathic type 1 DM is unknown, but it is not believed to be from an autoimmune process. Idiopathic type 1 DM is most frequently seen in patients of African and Asian descent. These patients have periods of profound hyperglycemia but only intermittently require insulin therapy.

④ Type 2 DM accounts for 90% to 95% of all cases of DM. The prevalence of type 2 DM in the United States is about 12.1% in adults.[2] The risk of developing type 2 DM increases with age and varies widely among racial and ethnic groups.[8] When compared to people of European ancestry, Native Americans, Latino/Hispanic Americans, African Americans, Asian Americans, and Pacific Islanders are more likely to develop type 2 DM. Whether the observed differences in the prevalence of type 2 DM among ethnic and racial groups is primarily due to genetic factors or social factors, such as lifestyle behaviors and cultural behaviors, is unclear. While the prevalence of type 2 DM increases with age, the disorder is increasingly being diagnosed in adolescence and young adulthood. This is likely due to the increasing incidence of obesity and lack of regular physical activity. Genetics plays an important role in the development of type 2 DM. Most cases of type 2 DM appear to be polygenic.

The incidence of GDM is increasing and, between 2007 and 2010, it was estimated to occur in 9% of all pregnancies in the United States.[9] Most women become normoglycemic after pregnancy; however, up to 50% of these women develop type 2 DM later in life.[10]

Other less common (1%-2%) forms of DM occur through a variety of mechanisms.[4] Maturity-onset diabetes of the young (MODY) and neonatal diabetes are inheritable forms of DM caused by specific single-gene mutations. Endocrine disorders, particularly acromegaly and Cushing syndrome, commonly induce hyperglycemia. Diseases that injure or destroy the pancreas such as cystic fibrosis, pancreatitis, and pancreatic cancer can damage β-cells and impair insulin secretion. Several medications can also contribute to hyperglycemia by either impairing insulin secretion, increasing insulin resistance, or both.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

① DM is caused by derangements in the secretion of insulin, glucagon, and other hormones and results in abnormal carbohydrate and fat metabolism.[6,8] This is often coupled with insulin resistance, particularly in those with type 2 DM. In many cases, the underlying etiology of the disorder is complex and involves multiple mechanisms.

After consuming food, carbohydrate ingestion increases the plasma glucose concentration and stimulates the release of incretin hormones from the gut and insulin release from the pancreatic β-cells.[8] The resultant hyperinsulinemia (1) suppresses hepatic glucose production, (2) suppresses glucagon release, and (3) triggers glucose uptake by peripheral tissues. Upwards of 75% of total body glucose disposal occurs in tissues, including the brain and peripheral nerves, which do not require insulin. Brain glucose uptake occurs at the same rate during fed and fasting periods. The remaining 25% of glucose metabolism takes place in the liver and muscle, tissues that require insulin to promote glucose uptake into the cells. During periods of fasting, approximately 85% of glucose is produced by the liver and the remainder by the kidney.

Although fat tissue is responsible for only a small portion of total body glucose disposal, it plays an important role in glucose homeostasis.[8] Insulin exerts a potent antilipolytic effect, reducing plasma-free fatty acid (FFA) levels. Increased levels of FFAs inhibit the uptake of glucose by muscle and stimulate hepatic gluconeogenesis. Lower FFA concentrations result in increased glucose uptake in muscle and indirectly reduce hepatic glucose production.

Glucagon is produced by pancreatic *α* cells and is secreted in the fasting state.[8] Glucagon stimulates hepatic glucose production and glycogenolysis. Glucagon and insulin secretion are closely linked. Appropriate secretion of both hormones is needed to keep plasma glucose concentrations within a normal range.

Type 1 Diabetes

Type 1 DM is the result of autoimmune destruction of the β-cells of the pancreas.[6] Given that insulin therapy is required when treating type 1 diabetes, it was previously called insulin-dependent diabetes mellitus, and some references, patients, and providers continue to use this, albeit incorrect, terminology. Type 1 DM is believed to be initiated by exposure to an environmental trigger in a genetically susceptible individual.[11] There is a link between currently known genetic markers for autoimmunity and the development of type 1 DM. However, β-cell autoimmunity develops in less than 10% of the genetically susceptible individuals and progresses to type 1 DM in less than 1%. On the other hand, β-cell autoimmunity, including ICAs, is present at the time of diagnosis in 90% of individuals. Type 1 diabetes most commonly develops in childhood or young adulthood; however, it can occur at any age. Children and adolescents typically have a more rapid rate of β-cell destruction and are more likely to present with DKA. Adults may maintain sufficient insulin secretion to prevent ketoacidosis for many months or years; this slowly progressive form of type 1 DM is sometimes referred to as LADA.

Several genetic polymorphisms have been linked to the development of type 1 DM, including certain human leukocyte antigens (HLA) class II alleles on chromosome 6.[11] Some genetic variants are associated with a higher risk of developing type 1 DM (eg, *DRB1*03-DQB1*0201, DRB1*04-DQB1*302*, and *HLA-B*39*) but others appear to be protective (eg, *DRB1*1501-DQA1*0102-DQB1*0602*). Genetic predisposition to the development of type 1 DM has also been associated with certain polymorphisms in the insulin gene region on chromosome 11. Other genes, including PTPN22, IL2RA, and CTLA-4, may also play a role in some individuals. However, it should be noted that genetic markers are present in only 30% to 50% of patients with type 1 DM. Moreover, only 50% of identical twins and approximately 10% of dizygotic twins develop type 1 DM. Thus, genetic mutations alone do not predict or explain the etiology of the disease.

In order for type 1 DM to develop, a genetically susceptible individual must be exposed to a trigger that initiates the autoimmune process and destruction of pancreatic β-cells.[11] See Fig. 94-1. However, it is unknown precisely what the inciting factors are. Several triggers have been implicated, including early exposure to cow's milk, lack of breastfeeding, gut bacteria (ie, intestinal microbiome), and certain viruses (eg, enterovirus and rotavirus). Although vitamin D deficiency is more prevalent in patients who develop type 1 DM, it is unclear if the relationship is causal or merely an association.

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β-cell antigens.[11] The most commonly detected antibody associated with type 1 DM is islet cell autoantibodies (ICAs). Other antibodies may be formed to insulin, glutamic acid decarboxylase 65 (GAD65), insulinoma-associated antigen-2 (IA-2), and zinc transporter 8 (ZnT8). These antibodies are generally considered markers of disease rather than mediators of β-cell destruction. These markers have been used to identify individuals at risk for type 1 DM and may be useful screening tests to initiate disease prevention strategies. Other autoimmune disorders such as Hashimoto's thyroiditis, Graves' disease, Addison's disease, vitiligo, and celiac sprue are more common in patients with type 1 DM.

In many patients who develop type 1 DM, there is a long preclinical period during which markers of autoimmunity can be detected.[11] β-Cell autoimmunity may precede the diagnosis of type 1 DM by up to 13 years. Autoimmunity remits in some individuals and progresses to absolute β-cell failure in others. Hyperglycemia occurs when 60% to 90% of the β-cells have been destroyed. After the initial diagnosis, there is occasionally a period of transient remission called the "honeymoon" phase during which insulin therapy may not be necessary. Eventually, continued β-cell destruction requires lifelong insulin replacement therapy.

Amylin is a hormone that is co-secreted from the pancreatic β-cell with insulin. Amylin is also deficient in patients with type 1 DM secondary to the destruction of β-cells. Amylin suppresses inappropriate glucagon secretion, slows gastric emptying, and centrally mediated satiety.

Type 2 Diabetes

Type 2 DM is the result of β-cell dysfunction coupled with some degree of insulin resistance.[8] Older references as well as some patients and practitioners continue to call this form of DM noninsulin-dependent diabetes or adult-onset diabetes. Both of these descriptors are erroneous because many patients with type 2 DM will require insulin therapy at some point as β-cell function progressively declines. Moreover, type 2 DM can develop in childhood and is increasingly diagnosed during adolescence. Most individuals with type 2 DM are overweight or obese. Abdominal adiposity is a major contributor to insulin resistance. Genetics play a critical role in the development of type 2 DM as there is a strong inheritance pattern. Hundreds of gene mutations have been linked to the development of type 2 DM. The majority of genetic mutations associated with type 2 DM appear to influence the development and function of β-cells, the sensitivity of cells to insulin action, or the development of obesity. However, none of these single-gene mutations have demonstrated a strong association with type 2 DM. Thus, type 2 DM is likely polygenetic, with more than one genetic defect contributing to its pathogenesis and a diverse combination of derangements contributing to its development in different populations.

In patients with type 2 DM, high blood pressure and dyslipidemia, characterized by high-serum triglycerides and low HDL-cholesterol levels, are very frequent comorbid conditions. Elevated serum plasminogen activator inhibitor-1 (PAI-1), which contributes to a hypercoagulable state, is also common. There are multiple risk factors for the development of type 2 DM.[12] See Table 94-2.

TABLE 94-2

Risk Factors for Type 2 Diabetes

Age ≥45 years old
Family history of type 2 DM (ie, parents or siblings with type 2 diabetes)
High-risk racial and ethnic groups (ie, African American, Hispanic/Latino, Native American, Asian American, Native Hawaiian, or Pacific Islander)
Overweight or obese (ie, ≥20% over ideal body weight or body mass index [BMI] ≥25 kg/m^2)
Sedentary lifestyle (ie, limited daily physical activity)
History of impaired glucose tolerance (IGT), impaired fasting glucose (IFG), or elevated A1C
Hypertension (≥140/90 mm Hg in adults or on therapy for hypertension)
Dyslipidemia (high-density lipoprotein [HDL] cholesterol ≤35 mg/dL (0.91 mmol/L) or a triglyceride level ≥250 mg/dL (2.83 mmol/L)
History of GDM or delivery of a baby weighing more than 9 lb (4 kg)
History of vascular disease (eg, myocardial infarction, ischemic stroke, peripheral arterial disease)
Presence of acanthosis nigricans (ie, dark, thick, and velvety skins around the neck or armpits)
Polycystic ovary syndrome

Most patients who develop type 2 DM have multiple defects that impact the regulation of plasma glucose: (1) impaired insulin secretion; (2) deficiency and resistance to incretin hormones; (3) insulin resistance involving muscle, liver, and adipocytes; (4) excess glucagon secretion; (5) increased hepatic glucose production; (6) upregulation of the sodium-glucose cotransporter in the kidney; (7) systemic inflammation; and (8) diminished satiety.[8] See Fig. 94-2.

The pancreas in people with normal-functioning β-cells is able to adjust insulin secretion to maintain normal plasma glucose levels. In obese individuals who do not yet have diabetes, insulin increases in proportion to the severity of the insulin resistance, and plasma glucose remains normal. Impaired insulin secretion is therefore requisite for the development of type 2 DM. In the early stages of β-cell dysfunction, first-phase insulin release is deficient, resulting in impaired glucose tolerance (IGT) (Fig. 94-3). First-phase insulin involves the release of stored insulin in the β-cell and acts to "prime" the liver for nutrient intake. Without appropriate first-phase insulin release, second-phase insulin must compensate for the subsequent postprandial carbohydrate load in order to normalize glucose levels. When insulin release is no longer sufficient to normalize plasma glucose, dysglycemia, including prediabetes and diabetes, ensue. In patients with type 2 DM, β-cell mass and function are both reduced. β-cell failure is progressive, starting years prior to the diagnosis of diabetes. People with type 2 DM lose approximately 5% to 7% of β-cell function per year. Progressive β-cell loss is likely the result of several factors, including (1) glucotoxicity; (2) lipotoxicity; (3) insulin resistance; (4) age; (5) genetics; and (6) incretin deficiency. Glucotoxicity occurs when glucose levels chronically exceed 140 mg/dL (7.8 mmol/L). The β-cell is unable to maintain sufficient insulin secretion and, paradoxically, releases less insulin as glucose levels increase.

FIGURE 94-3

Natural history of type 2 diabetes. (IGT, impaired glucose tolerance.) For several years prior to the onset of overt hyperglycemia, β-cell dysfunction and the progressive loss of β-cells begins. Moreover, resistance to the action of insulin in muscle and fat tissue is accelerated by weight gain and central adiposity . With increasing insulin resistance and β-cell dysfunction, post-prandial blood glucose concentrations become abnormal . However, fasting blood glucose concentrations typically remain normal or only slightly elevated. As β-cell loss continues, fasting blood glucose readings begin to rise. It is at this point that most patients are diagnosed. Initial treatments improve glycemic control by improving insulin secretion or reducing insulin resistance, or both. Over time, as β-cell loss continues and insulin secretion dwindles to <20% of normal, near-normal blood glucose concentrations can not be achieved without supplemental insulin therapy. Blood glucose values in mg/dL can be expressed in mmol/L by multiplying by 0.0555.

Gestational Diabetes

GDM develops during pregnancy.[13] If DM is diagnosed prior to pregnancy, this is not GDM, but rather pregnancy with preexisting DM. Hormone changes during pregnancy result in increased insulin resistance, and GDM may ensue if the mother cannot increase insulin secretion to adequately compensate to maintain normoglycemia. Women who develop GDM are predisposed to subsequently developing type 2 DM. GDM and type 2 DM likely share much of the same etiological causes. In most cases, glucose intolerance first appears near the beginning of the third trimester. However, risk assessment and intervention should begin from the first prenatal visit. Detection is important, as therapy will reduce perinatal morbidity and mortality.

Other Types of Diabetes

MODY is characterized by impaired insulin secretion in response to a glucose stimulus with minimal or no insulin resistance.[4] Patients typically exhibit mild hyperglycemia at an early age, and diagnosis is often delayed. The disease is inherited in an autosomal-dominant pattern with at least six different mutations identified to date. MODY 2 and 3 are most common.

The production of mutant insulin molecules has been identified in a few families and also results in abnormal glucose intolerance. Several genetic mutations have been described in the insulin receptor and are associated with insulin resistance. Type A insulin resistance is a clinical syndrome characterized by acanthosis nigricans, virilization in women, polycystic ovaries, and hyperinsulinemia. Anti-insulin receptor antibodies may block the binding of insulin. This has been referred to as type B insulin resistance.

CLINICAL PRESENTATION

Characteristic	Type 1 DM	Type 2 DM
Typical age at diagnosis	<20 years[a]	>30 years[b]
Body habitus	Lean (BMI < 25 kg/m^2)	Overweight or obese (BMI > 25 kg/m^2); abdominal obesity and increased waist:hip ratio
Family history of DM in first-degree relatives	Uncommon (<10%)	Common (>80%)
Insulin resistance	Uncommon (occurs if obese)	Very common
Autoantibodies	Usually present	Rarely present
Onset	Abrupt (days/weeks)	Gradual (years)
Symptoms[c]	Common and may be dramatic	Uncommon and often mild
Ketosis	Prone	Rare
Acute complication	Diabetic ketoacidosis (DKA)	Hyperosmolar hyperglycemic state (HHS)
Need for insulin replacement therapy	Immediate	Years after diagnosis
Long-term complications present at diagnosis	Rare—screening for complications unnecessary	Common—screening for complications recommended

[a] While most patients are diagnosed before age 20, type 1 DM can occur at any age.

[b] While most patients are diagnosed after age 30, type 2 DM is increasingly common in obese adolescents and young adults, especially in high-risk populations (eg, Black Americans, Latino/Hispanic Americans, Native Americans)

[c] The classic symptoms of DM include polyuria, polydipsia, polyphagia, weight loss, and fatigue.

The clinical presentation and features of type 1 DM and type 2 DM are different. Although type 1 DM can develop at any age, most patients are diagnosed before the age of 20. Patients with type 1 DM are often lean or thin at the time of diagnosis. In the absence of an adequate supply of insulin, patients with type 1 DM are prone to developing ketoacidosis and many initially present with DKA. Patients with type 1 DM often have symptoms in the days or weeks preceding the diagnosis. These symptoms often include frequent urination (polyuria) due to an osmotic diuresis from glucosuria, excessive thirst (polydipsia) due to dehydration, increased appetite (polyphagia), and weight loss due to caloric loss. Fatigue and lethargy are also common. The onset of symptoms can be triggered by an infection, trauma, or psychological stress.

In contrast, a majority of patients with type 2 DM are asymptomatic or have only mild fatigue at the time of diagnosis. Many patients are incidentally discovered to have type 2 DM based on the results of a routine laboratory test (eg, plasma glucose or A1C) or development of complications (eg, myocardial infarction, stroke, kidney impairment). Mild hyperglycemia is likely present for many years prior to the diagnosis and thus explains why both microvascular and macrovascular complications are often present at the time of diagnosis. Most patients with type 2 DM are overweight or obese with an elevated waist:hip ratio. Many will report having first-degree relatives with diabetes.

Diagnosis of Diabetes

⑤ The diagnosis of diabetes requires the use of glycemic cut points that discriminate patients with normal BG from patients with IFG, IGT, and diabetes (Tables 94-4 and 94-5). The cut points are meant to reflect the level of glucose above which microvascular complications have been shown to increase.[4] Cross-sectional studies have shown a consistent increase in the risk of developing retinopathy at an FPG level above 116 mg/dL (6.4 mmol/L), a 2-hour PPG level above 185 mg/dL (10.3 mmol/L), and an A1C above 6.0% (0.060; 41-42 mmol/mol).

TABLE 94-3

Definitions of Normal and Abnormal Glycemia

Fasting plasma glucose (FPG)	
Normal fasting glucose	70-99 mg/dL (3.9-5.5 mmol/L)
Impaired fasting glucose (IFG)	100-125 mg/dL (5.6-6.9 mmol/L)
Diabetes mellitus	≥126 mg/dL (7.0 mmol/L)
2-hour post-load plasma glucose (oral glucose tolerance test)	
Normal glucose tolerance	<140 mg/dL (7.8 mmol/L)
Impaired glucose tolerance (IGT)	140-199 mg/dL (7.8-11.0 mmol/L)
Diabetes mellitus[a]	≥200 mg/dL (11.1 mmol/L)
Glycosylated hemoglobin (A1C)	
Normal A1C	4-5.6% (0.04-0.056; 20-38 mmol/mol)
Increased risk of diabetes mellitus (Prediabetes)	5.7-6.4% (0.057-0.064; 39-46 mmol/mol)
Diabetes mellitus	≥6.5% (0.065; 48 mmol/mol)

Data from Reference 4.

If an NGSP (previously known as the National Glycohemoglobin Standardization Program) method is used, the A1C is the logical test for the diagnosis of diabetes as it measures glycemic exposure over the last 2 to 3 months, in contrast to a single-day, single-point glucose measurement. In addition, patients do not need to fast, and the A1C is a readily available test. An A1C of 6.0% to 6.4% (0.06-0.064; 42-46 mmol/mol) denotes a 10-fold increase in the risk of developing diabetes but does not consistently identify patients with impaired fasting glucose or impaired glucose tolerance. There are slight racial differences in normal A1C levels. One-third fewer individuals with diabetes are identified using the A1C ≥ 6.5% (0.065; 48 mmol/mol) threshold versus an FPG ≥ 126 mg/dL (7.0 mmol/L), yet providers may be more likely to diagnose diabetes from an A1C than from an elevated FPG level. While an A1c ≥ 6.5% (0.065; 48 mmol/mol) is perhaps the most convenient and sensitive method of diagnosing DM, there are three other criteria that can be used to diagnose DM in nonpregnant adults. See Table 94-4. If the patient has symptomatic hyperglycemia and a random plasma glucose ≥200 mg/dL (11.1 mmol/L), reconfirming the diagnosis is not required.

TABLE 94-4

Criteria for the Diagnosis of Diabetes Mellitus

1. A1C ≥6.5% (0.065; 48 mmol/mol). The test should be performed in a laboratory using a method that is NGSP certified and standardized to the Diabetes Control and Complications Trial (DCCT) assay.[a]
2. Fasting plasma glucose ≥126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.[a]
3. Two-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.[a]
4. In a patient with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose concentration ≥200 mg/dL (11.1 mmol/L).

[a] In the absence of unequivocal hyperglycemia, a diagnosis requires two abnormal test results from the same sample or in two separate test samples.

Data from Reference 4.

Serial measurements at clinician-defined intervals can help to identify patients moving toward diabetes and those who are stable. Patients who have even minor increases in glucose or A1C values over time should be followed more closely as they are more likely to progress to DM. The A1C measurement can be affected by anemias and several hemoglobinopathies, which would necessitate the use of one of the plasma glucose criteria in these individuals. More information about the A1C assay can be found at the NGSP website: http://www.ngsp.org/interf.asp.

Screening for Diabetes

Given the long-term complications associated with DM and the positive impact that early interventions can have on hyperglycemia and health outcomes, efforts to screen at-risk patients for impaired FPG and the development of diabetes are recommended. Screening begins with identifying patients who are at risk for developing diabetes and, once identified, encouraging patients to obtain an FPG and A1C measurement.

Type 1 Diabetes

The prevalence of type 1 DM is low in the general population. Due to the acute onset of symptoms in most individuals, screening for type 1 DM in asymptomatic children or adults is not recommended.[4] Screening for β-cell autoantibody status in high-risk family members may be appropriate in the context of clinical research trials for the prevention of type 1 DM.

Type 2 Diabetes

The ADA recommends screening for type 2 DM in adults who are overweight (BMI ≥ 25 kg/m^2 or ≥23 kg/m^2 in Asian-Americans) and have at least one other risk factor for the development of type 2 DM.[4] See Table 94-2. The risk of type 2 DM increases with age, and therefore all adults, even those without risk factors, should be screened every 3 years starting at 35 years old. The recommended screening tests are an FPG, A1C, or 2-hour oral glucose tolerance test (OGTT). The optimal time between screening tests is not known, but it may be prudent to screen patients with multiple risk factors every year.

Children and Adolescents

Despite a lack of clinical evidence to support widespread testing of children for type 2 DM, it is clear that more children and adolescents are developing type 2 DM. The ADA recommends screening overweight (defined as BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal) youths who have at least one of the following risk factors: a family history of type 2 DM in first- and second-degree relatives; Native Americans, African Americans, Hispanic Americans, and Asians/South Pacific Islanders; those with signs or conditions associated with insulin resistance (eg, acanthosis nigricans, hypertension, dyslipidemia); or maternal history of diabetes or GDM during the child's gestation.[4] Screening should be done every 3 years starting at age 10 years or at the onset of puberty if it occurs at a younger age.

Gestational Diabetes

Risk assessment for GDM should occur at the first prenatal visit. Due to the high prevalence of obesity and undiagnosed DM, women with multiple risk factors for type 2 DM should be tested as soon as feasible.[4] All women, even if the initial screen test at the first prenatal visit was negative, should undergo testing between weeks 24 and 28 of gestation. Screening for GDM may be done in one of two ways: (1) a one-step strategy using a fasting 75-g OGTT, or (2) a two-step strategy starting with a nonfasting 50-g glucose load test (GLT). With the standard 75-g OGTT, the diagnosis of GDM is confirmed when fasting, 1-hour, 2-hour, and/or 3-hour glucose values are equal or greater to cut-off values. If a nonfasting 50-g GLT is performed, a fasting 100-g glucose tolerance test must be performed if the 1-hour value is elevated. See Table 94-5.

TABLE 94-5

Screening for and Diagnosis of Gestational Diabetes Mellitus (GDM)

1. One-step method (fasting 75-g OGTT)[a]	
One abnormal value is diagnostic of GDM	
Time	**Plasma Glucose**
Fasting	≥92 mg/dL (5.1 mmol/L)
1 hour	≥180 mg/dL (10.0 mmol/L)
2 hours	≥153 mg/dL (8.5 mmol/L)
2. Two-step method	
Step 1: Perform a 50-g OGTT (nonfasting) at 24-28 weeks of gestation in women not previously diagnosed with diabetes	
1 hour	≥140 mg/dL[b] (7.8 mmol/L)
Step 2: If a screening test is positive, perform 100-g OGTT (fasting)	
Two or more abnormal values are diagnostic for GDM	
Fasting	95 mg/dL (5.3 mmol/L)
1 hour	180 mg/dL (10.0 mmol/L)
2 hours	155 mg/dL (8.6 mmol/L)
3 hours	140 mg/dL (7.8 mmol/L)

[a] Should be performed at 24-28 weeks gestation unless the patient has diabetes. The test should be done in the morning after an 8- to 14-hour fast.

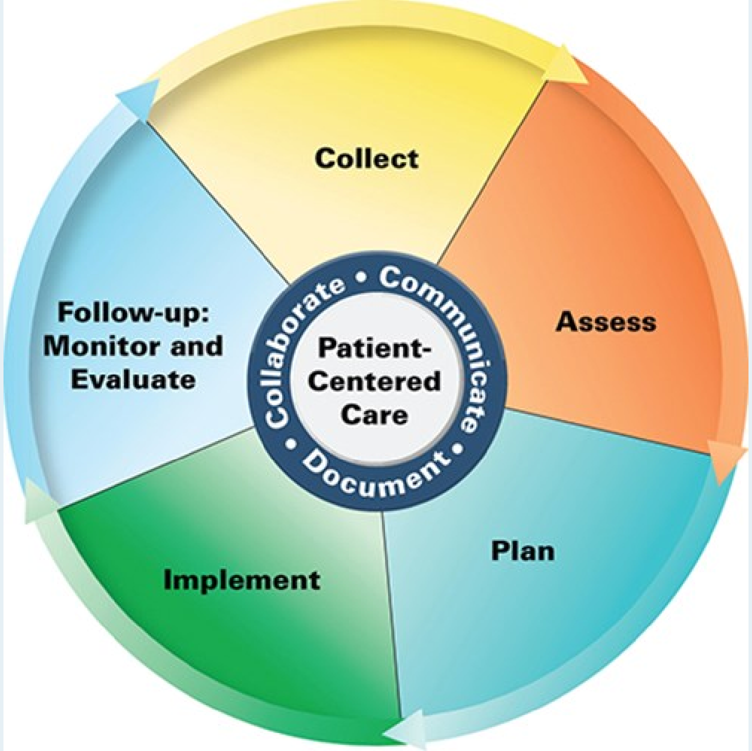
[b] The ACOG recommends a lower threshold of 135 mg/dL (7.5 mmol/L) in high-risk ethnic populations with a higher prevalence of GDM; some experts also recommend 130 mg/dL (7.2 mmol/L).

Data from Reference 4.

PATIENT CARE PROCESS

PATIENT CARE PROCESS

Patient Care Process for the Management of Diabetes Mellitus



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, sex, reproductive status)
- Characteristics of diabetes (eg, type, age of onset, initial presentation)
- Microvascular and macrovascular complications
- Hypoglycemia episodes, symptoms, frequency, and suspected cause(s)
- History of diabetic ketoacidosis (DKA) or hyperosmolar hyperglycemic syndrome (HHS)—frequency, severity, and suspected cause(s)
- Patient history (past medical, family, social—dietary habits, weight history, sleep behaviors, physical activity)
- Current medications (including complementary and alternative therapies) and medication-taking behaviors (eg, adherence, injection technique)
- Past diabetes treatments, response to therapy, the reason for discontinuation
- Diabetes and nutritional education (currently enrolled and completed)

- Self-monitoring of blood glucose (SMBG) or continuous glucose monitoring (CGM) results and self-management behaviors
- Social and cultural issues—preferences, values, and beliefs; health literacy
- Physical exam: height, weight, BMI, blood pressure, heart rate, comprehensive foot exam
- Labs (eg, glucose, hemoglobin A1c [A1C], serum creatinine [Scr], blood urea nitrogen [BUN], estimated glomerular filtration rate [eGFR], fasting lipid panel [FLP], urine albumin to creatinine ratio [UACR], serum electrolytes)

Assess

- Diagnosis and classification (see Tables 94-1, 94-3, and 94-4)
- Microvascular and macrovascular complications and potential comorbid conditions
- Achievement of A1C and glycemic goals (see Table 94-6)
- Appropriateness, effectiveness, safety/tolerability, treatment burden, cost, and adherence to the current antihyperglycemic regimen
- Achievement of weight, lifestyle, and other behavioral goals
- Achievement of goals for comorbidities (eg, blood pressure, lipids, neuropathic pain)
- Screen for depression, anxiety, disordered eating
- Screen for psychosocial problems and barriers to diabetes self-management

Plan[*]

- Appropriate A1C and glycemic goals based on age, comorbidities, and other factors (see Table 94-6)
- Tailored lifestyle modifications (eg, diet, exercise, weight management)
- Drug therapy regimen including specific antihyperglycemic agent(s), dose, route, frequency, and duration; specify continuation and discontinuation of existing therapies (see Tables 94-7, 94-8, 94-9, 94-10, and 94-11)
- Monitoring parameters including efficacy (eg, A1C, SMBG), safety (medication-specific adverse effects, hypoglycemia), and timeframe (see Table 94-11)
- Patient education (eg, the purpose of treatment, drug administration, dietary and lifestyle modification)
- Referrals to other providers when appropriate (eg, diabetes care and education specialist, registered dietician, eye care professional, podiatrist, mental health professional)

Implement[*]

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up including telehealth visits to monitor and adjust treatment

Follow-Up: Monitor and evaluate

- Determine A1C and glycemic goal attainment
- Identify the presence of medication-related adverse effects (see Table 94-10)

- Assess occurrence/development/progression of diabetes-related complications
- Evaluate patient adherence to treatment plan using multiple sources of information

Collaborate with patient, caregivers, and other healthcare professionals.

TREATMENT

General Approach to Treatment

During an initial visit, a thorough medical evaluation should be completed to confirm the diagnosis, classify the type of diabetes, evaluate for any complications or potential comorbid conditions, and review previous treatments and risk factors in established patients. Past medical, family, and social history should be taken as well as medication use, adherence, tolerability, and use of diabetes technology. Screening for psychosocial conditions, self-management education needs, and hypoglycemia should occur. A thorough physical exam (including height, weight, BMI, blood pressure, thyroid palpitation, and foot exam) and laboratory evaluation (including A1C, lipid profile, liver function tests, serum creatinine, and eGFR) should be performed. A 10-year atherosclerotic cardiovascular disease (ASCVD) risk score should also be calculated.[14,15]

Goals of Therapy

⑥ ⑦ The primary goals of therapy for DM are to prevent or delay the progression of long-term micro- and macrovascular complications including retinopathy, neuropathy, diabetic kidney disease, and ASCVD. Additional goals of therapy are to alleviate symptoms of hyperglycemia, minimize hypoglycemia and other adverse effects, minimize treatment burden, and maintain quality of life. This requires glycemic control as well as control of comorbidities and CV risk factors. Glycemic control has well-documented benefits in terms of reducing both short-term and long-term complications associated with DM, but overly intensive control has also led to poor outcomes. Thus, glycemic targets should be individualized for each patient and should be based on balanced considerations of clinical trial evidence and patient-specific factors.[15,16]

Evidence to Support Intensive Glycemic Control

The first trial to definitively prove that good glycemic control could prevent or delay diabetes-related complications was the Diabetes Complications and Control Trial (DCCT).[17] The DCCT enrolled patients with type 1 DM. Patients in the intensive group were treated with intensive basal-bolus insulin therapy (three or more insulin injections per day or insulin pump), with frequent alterations of insulin therapy based on self-monitoring of blood glucose (SMBG) results plus frequent contact with a health professional. Patients in the conventional therapy were treated with one or two insulin injections per day. After 6.5 years, retinopathy, neuropathy, and nephropathy were significantly reduced in the intensive group, but symptomatic and severe hypoglycemia was significantly more frequent. Long-term follow-up of the trial participants demonstrated a reduction in macrovascular complications as well as persistent reductions in microvascular complications, even though the difference in A1C values between treatment groups disappeared over time.[18,19]

Another landmark clinical trial, The United Kingdom Prospective Diabetes Study (UKPDS), enrolled more than 5,000 patients with type 2 DM between 1977 and 1991. Patients were followed for an average of 10 years to determine the impact of intensive versus conventional glycemic control on the incidence of long-term complications in patients with newly diagnosed type 2 DM. The results showed that intensive glycemic control (using sulfonylureas and insulin) achieved an A1C of 7.0% (0.070; 53 mmol/mol) compared to 7.9% (63 mmol/mol) in the conventional group. This translated into a modest but significant (12%) reduction in diabetes-related complications, most of which was due to a 25% reduction in microvascular complications.[20] Intensive glucose control using metformin as the initial therapy lowered the risk of diabetes-related complications by 32%, diabetes-related death by 42%, and all-cause mortality by 36% compared to conventional treatment in an overweight cohort of patients.[21] In the long-term UKPDS follow-up study, microvascular benefits of good glycemic control persisted 10 years after the end of the original trial, and a significant long-term reduction in myocardial infarction (MI) and all-cause mortality emerged in the intensive glucose control arm.[22]

Three additional large clinical trials were performed after the UKPDS to compare the effects of different intensities of glycemic control on the risk of macrovascular complications. These studies were done in patients with long-standing type 2 DM who were at high risk for ASCVD. The Action to Control

CV Risk in Diabetes (ACCORD) study showed that lower A1C levels (achieved mean A1C 6.4% vs 7.5% [0.064 vs 0.075; 46 vs 58 mmol/mol]) reduced the risk of some microvascular complications but did not reduce the risk of macrovascular complications. The risk of hypoglycemia was significantly higher in the intensive treatment group. Most importantly, this study was stopped early due to an increase in mortality in the intensive treatment arm.[23] The Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation (ADVANCE) study similarly showed no significant differences in ASCVD outcomes between two levels of glycemic control (achieved mean A1C 6.3% vs 7.0% [0.063 vs 0.070; 45 vs 53 mmol/mol]) but did show that the more intensive glucose control reduced microvascular complications.[24] The Veterans Affairs Diabetes Trial (VADT) also suggested reduced microvascular complications but no significant reduction in ASCVD outcomes with more intensive glycemic control (6.9% vs 8.5% [0.069 vs 0.085; 52 vs 69 mmol/mol).[25] Based on the results of these studies in aggregate, there appear to be some benefits in terms of microvascular complications but not ASCVD outcomes from intensive glycemic control. However, achieving more stringent glucose targets requires more intensive treatment, which is often more complex and costly, and increases the risk of severe hypoglycemia when insulin therapy is used. The short-term and long-term benefits and risks must be carefully considered when setting intensive glycemic targets.

Glycemic Targets

Based on the clinical evidence that glycemic control reduces microvascular complications and also has long-term benefits in reducing macrovascular complications, several organizations, including the ADA and AACE, recommend surrogate targets for glycemic control. The ADA Standards of Care indicate that an A1C < 7% (0.07; 53 mmol/mol) is reasonable for most nonpregnant adults. A fasting or preprandial plasma glucose (FPG) target range of 80 to 130 mg/dL (4.4 and 7.2 mmol/L) and a peak postprandial plasma glucose (PPG) target of <180 mg/dL (10.0 mmol/L) (1-2 hours after the beginning of a meal) correspond with an A1C target <7% (0.07; 53 mmol/mol).[16] The AACE guidelines are more aggressive and indicate that an A1C ≤ 6.5% (0.065; 48 mmol/mol) is optimal if it can be achieved in a safe and affordable manner. An FPG target of <110 mg/dL (6.1 mmol/L) and a 2-hour PPG target of <140 mg/dL (7.8 mmol/L) correspond with this recommendation (Table 94-6).[26]

TABLE 94-6

Glycemic Target Recommendations in Various Populations

Glycemic targets for most nonpregnant adults with diabetes[a]		
	American Diabetes Association (ADA)	American Association of Clinical Endocrinologists (AACE)
Glycosylated hemoglobin (A1C)	<7.0% (0.07; 53 mmol/mol)	≤6.5 (0.065; 48 mmol/mol)
Fasting/preprandial plasma glucose (FPG)	80-130 mg/dL (4.4-7.2 mmol/L)	<110 mg/dL (6.1 mmol/L)
Peak postprandial glucose (PPG)	<180 mg/dL (10.0 mmol/L)	<140 mg/dL (7.8 mmol/L)
Time in range (TIR); % of CGM readings and time between 70 and 180 mg/dL (3.9-10.0 mmol/L)	>70%	
Time below range (TBR); % of CGM readings and time <70 mg/dL (3.9 mmol/L)	<4%	
Glycemic variability (% CV)	≤36%	
American Diabetes Association glycemic targets for adolescents and children		
A1C	<7.0% (0.07; 53 mmol/mol)	
FPG/preprandial glucose	90-130 mg/dL (5.0-7.2 mmol/L)	

Bedtime or overnight glucose	90-150 mg/dL (5.0-8.3 mmol/L)		
American Diabetes Association glycemic targets for pregnant women			
A1C	<6.5% (0.065; 48 mmol/mol)		
FPG or premeal glucose	<95 mg/dL (5.3 mmol/L)		
Postprandial glucose (1 hr)	<140 mg/dL (7.8 mmol/L)		
Postprandial glucose (2 hr)	<120 mg/dL (6.7 mmol/L)		
American Diabetes Association glycemic targets for older adults			
Patient characteristics/health status	A1C	FPG or preprandial glucose	Bedtime glucose
Healthy (few coexisting chronic illnesses, intact cognitive and functional status)	<7.0%-7.5% (0.07-0.075; 53-58 mmol/mol)	80-130 mg/dL (4.4-7.2 mmol/L)	80-180 mg/dL (4.4-10 mmol/L)
Complex/intermediate (multiple coexisting chronic illnesses or 2+ instrumental ADL impairments or mild-to-moderate cognitive impairment)	<8.0% (0.080; 64 mmol/mol)	90-150 mg/dL (5.0-8.3 mmol/L)	100-180 mg/dL (5.6-10.0 mmol/L)
Very complex/poor health (LTC or end-stage chronic illnesses or moderate-to-severe cognitive impairment or 2+ ADL dependencies)	Avoid reliance on A1C; avoid hypoglycemia and symptomatic hyperglycemia	100-180 mg/dL (5.6-10.0 mmol/L)	110-200 mg/dL (6.1-11.1 mmol/L)

ADL, activities of daily living; CGM, continuous glucose monitoring; CV, coefficient of variation; LTC, long-term care

[a] Glycemic targets should be individualized. More or less stringent goals may be appropriate for some patients.

Many patients now use a CGM device to assist with glucose management. The use of a CGM can be beneficial for many patients with diabetes and is recommended in patients who use intensive insulin therapy and for those who experience severe or frequent hypoglycemia. A CGM device can report the percentage of time in, above, and below the recommended target ranges and can report the variability of glucose readings. Ideally, the time in range, defined as 70 to 180 mg/dL (3.9 to 10.0 mmol/L), should be at least 70% and the time below range, defined as <70 mg/dL (3.9 mmol/L), should be less than 4%. A CGM device can also report glucose variability, an outcome that is increasingly being recognized as a clinically meaningful outcome beyond A1C. Emerging data indicates that, regardless of A1C, fluctuations in glucose are associated with increased risk of diabetes complications, and A1C alone does not provide the full picture of glycemic control (see Fig. 94-4). Glucose variability is defined as the percent coefficient of variation (%CV) and should be ≤36%.[16] These glucose statistics can be viewed through the ambulatory glucose profile (AGP) report, which also includes a summary glucose profile graph and daily glucose graphs (see Fig. 94-5). The AGP report is a standardized, single-page report that is easy to interpret and provides consistent data regardless of what device is being used.[27]

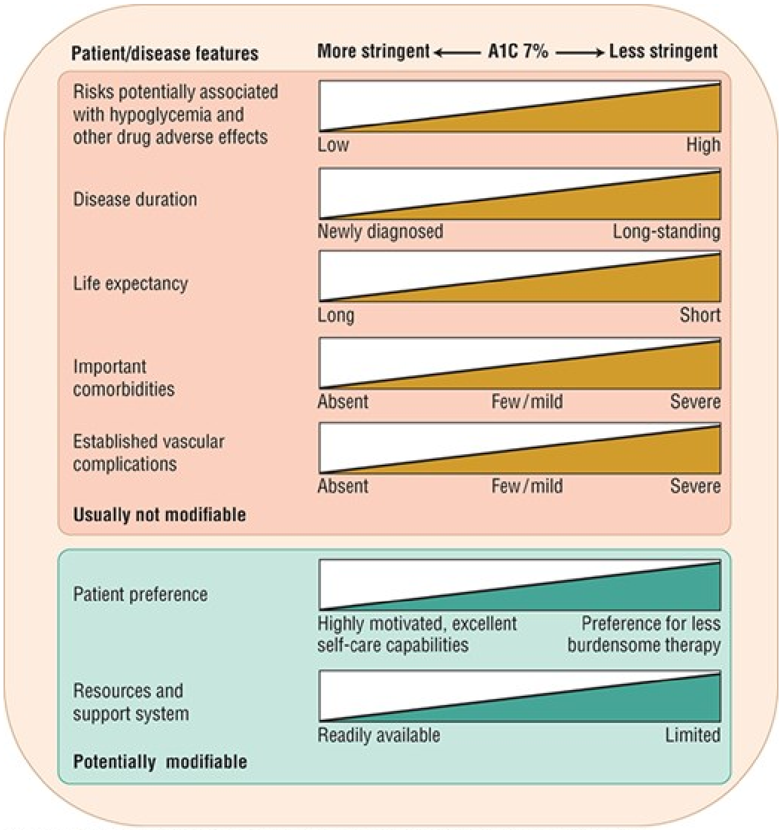
Glycemic targets must be individualized based on patient-specific factors and the potential risks and benefits of treatment (see Fig. 94-6). Ideally, glycemic targets should be established at the time of diagnosis and should be reviewed and re-evaluated at each visit. When possible, these decisions should be made in collaboration with the patient. Patient or disease factors to consider include treatment-related risks including hypoglycemia and other adverse effects, ability to sense or articulate hypoglycemia symptoms, disease duration, life expectancy, comorbidities, established vascular complications, patient attitude and expected treatment effort, access to CGM or other resources, and support system. While an A1C < 7% (0.07; 53

mmol/mol) is recommended for most patients, a more stringent goal (such as <6.5% [0.065; 48 mmol/mol]) may be appropriate for some patients if it can be achieved without significant adverse effects, particularly hypoglycemia. Those patients might be younger, with a long life expectancy, with a short duration of diabetes, those treated only with lifestyle modifications or metformin, or those without significant comorbidities. Less stringent goals (such as <8% [0.08; 64 mmol/mol]) may be appropriate for patients who are older or who have a long duration of diabetes, a history of severe hypoglycemia, extensive serious comorbidities, or advanced complications. A higher A1C goal may also be appropriate for a patient in whom it remains difficult to achieve the goal despite appropriate education, monitoring, and drug therapy. For those treated with complex medication regimens, especially those that include insulin, the risk of trying to achieve stringent glycemic goals may outweigh the benefit.

FIGURE 94-6

Approach to individualizing glycemic targets. (*Adapted from American Diabetes Association)* Higher A1C goals should be considered in adolescents and children as well as patients older than 65 years (Table 94-6).[28] An A1C goal < 7.5% (0.075; 58 mmol/mol) is reasonable for healthy older adults, while an A1C goal < 8.0% (0.080; 64 mmol/mol) should be considered for those with coexisting chronic diseases, impairments of activities of daily living, cognitive impairment, or who reside in long-term care facilities. In older adults with limited life expectancy, multiple comorbid conditions, or limited cognition, the A1C should not be used to guide therapy.



Patient/disease features
More stringent ← A1C 7% → Less stringent
Risks potentially associated with hypoglycemia and other drug adverse effects
Low
High
Disease duration

NONPHARMACOLOGIC THERAPY

8 Nonpharmacologic therapy such as medical nutrition therapy (MNT), physical activity, glucose monitoring, and diabetes self-management education (DSME) is a cornerstone of treatment for all patients with diabetes.

Medical Nutrition Therapy

MNT is an evidence-based medical approach to treating diabetes through the use of an individually tailored nutrition plan. There is no standardized "diabetes diet," nor is there a single ideal distribution of macronutrients; therefore, meal planning should be individualized. It is imperative that patients understand the interrelationships between carbohydrate intake, medications, weight, and glucose control. A healthy meal plan that is moderate in calories and carbohydrates and low in saturated fat, with all of the essential vitamins and minerals, is recommended. A Mediterranean-style diet rich in mono- and polyunsaturated fats may have glucose and CV benefits and could be considered.[29]

Weight loss or weight maintenance is a crucial element in many patients with type 2 DM. An initial weight loss goal of at least 5% should be targeted in all patients who are overweight or obese through calorie restriction. Strategies to reduce calories include reducing portions and frequency of food intake, decreasing the consumption of empty calories, added sugars, and saturated fats, increasing nutrient-dense foods (eg, nonstarchy vegetables), employing low-calorie cooking methods, and tracking calorie intake. Helping the patient adopt healthier eating behaviors that lead to sustained weight loss over time is more important than a specific diet.[29]

Carbohydrate counting is another valuable component of diabetes care. The appropriate amount (grams) and type of carbohydrates are controversial. For individuals with type 1 DM, the focus is more on physiologically regulating insulin administration. For those on fixed doses of mealtime insulin, consistent intake of carbohydrates is recommended to improve glucose control and minimize hypoglycemia. For those on flexible insulin dosing regimens (eg, matching insulin doses to carbohydrate intake amounts), accurate carbohydrate counting to determine mealtime insulin doses is required. For patients with type 2 DM, carbohydrate counting focuses more on a balanced diet with moderate carbohydrate intake at each meal to minimize glucose excursions. Carbohydrate intake from vegetables, fruits, legumes, whole grains, dairy products, and those high in fiber is preferred. Sugar-sweetened beverages and foods with added sugars should be discouraged. Financial constraints and cultural food practices must also be considered. Discourage bedtime and between-meal snacks, set realistic goals, determine what the patient is willing to change, and follow-up to see how and whether those changes were implemented.[29]

Physical Activity

Most patients with diabetes benefit from regular physical activity. Aerobic exercise improves insulin sensitivity, modestly improves glycemic control in the majority of individuals, reduces CV risk, contributes to weight loss or maintenance, and improves well-being. Patients should choose activities that they enjoy and are likely to do at regular intervals. Start exercise slowly in previously sedentary patients. It is unclear if asymptomatic patients should be screened for ASCVD prior to beginning an exercise regimen. Screening is reasonable in patients with long-standing disease (more than or equal to 10 years), multiple CV risk factors, microvascular disease (especially kidney disease), or evidence of atherosclerotic disease. If the patient has uncontrolled hypertension, autonomic neuropathy, insensate feet, or proliferative retinopathy, restrictions on recommended activities are recommended. Physical activity goals include at least 150 minutes per week of moderate (50%-70% maximal heart rate) intensity exercise spread over at least 3 days a week with no more than 2 days between activities. In addition, resistance/strength training is recommended at least two times a week as long as the patient does not have proliferative diabetic retinopathy.[29]

Glucose Monitoring

Patients with diabetes should be reassessed every 3 to 6 months (3 months if uncontrolled and 6 months if controlled). An A1C should be drawn, and treatment should be adjusted as needed.[16]

Patients on intensive insulin therapy should SMBG at least four times daily, before meals and at bedtime, or should use a CGM device. Patients should also test before exercise, prior to critical tasks such as driving, and if symptoms of hypoglycemia occur. SMBG or CGM use is crucial during times of intercurrent illness to detect and prevent acute hyperglycemic complications such as DKA. Patients may also benefit from occasionally testing 2 hours after meals.[16]

Continuous glucose monitors report interstitial glucose levels in real-time and provide insight into glucose trends. Data from these devices can be used for insulin dose calculations, and some are integrated with insulin pumps. CGM use with intensive insulin therapy can reduce A1C, hypoglycemia, and glucose variability. Current guidelines support the use of CGM in patients on intensive insulin therapy. CGM is also recommended in patients with hypoglycemia unawareness to better detect and prevent hypoglycemic events.[76]

Diabetes Self-Management Education and Support (DSME/S)

Consistent, long-term diabetes control requires patients to have a good understanding of their disease and participate in routine self-management strategies to control it. All patients should be offered access to diabetes self-management education and support (DSME/S) programs. There are four critical times to evaluate the need for DSME/S: at diagnosis, annually, when complicating factors arise, and when transitions in care occur.[29] The Association of Diabetes Care and Education Specialists (ADCES) has identified seven self-care behaviors that can be targeted through DSME/S. The behaviors include healthy eating, being active, monitoring, taking medications, problem-solving, reducing risk, and healthy coping.[30] The patient must be involved in the decision-making process and the process must be collaborative. Emphasize that complications can be prevented or minimized with good glycemic control and managing risk factors for ASCVD. Motivational interviewing techniques have been shown to be effective. Briefly, this involves asking open-ended questions that encourage patients to identify and acknowledge barriers that hinder achieving health goals, and then work to address them with the educator's guidance.

Health professionals with formal training and experience in diabetes education can become certified. A certified diabetes care and education specialist (CDCES) must document their experience providing patient education and pass a certification examination. An increasing number of nurses, pharmacists, dietitians, and physicians are becoming a CDCES. Formal diabetes education programs often employ several health professionals including a CDCES. Accredited diabetes education programs can receive payment through Medicare and private health insurance plans. The AADE and ADA accredit diabetes education programs. It must be noted, however, that there are not enough practitioners who hold the CDCES credential to provide education to all patients with diabetes. Therefore, all healthcare professionals must be well-versed in the educational needs related to diet, physical activity, and other self-care behaviors to provide education and reinforcement of these crucial management strategies. Finally, patients should be advised not to smoke, and smoking cessation counseling should be a routine component of diabetes care.

PHARMACOLOGIC THERAPIES

Insulin

Endogenously produced insulin is cleaved from the larger proinsulin peptide in the β-cell to the active peptide of insulin and inactive C-peptide. All commercially available insulin preparations contain only the active insulin peptide and are produced and manufactured exclusively using recombinant DNA technology. “Human” insulins (NPH, regular) are recombinant DNA–derived human insulin, while insulin analogs have had amino acids substitutions in the insulin molecule that change the onset or duration of action. Most insulin products are administered subcutaneously for the chronic management of diabetes, except for inhaled human insulin which is a dry powder of human recombinant DNA regular insulin which is inhaled and absorbed through pulmonary tissue. The main advantage of insulin over other antihyperglycemic agents is that it can achieve a wide range of glucose targets and the dose can be individualized based on glycemic levels. Disadvantages include the risk of hypoglycemia, the need for injection(s), weight gain, and treatment burden.

Insulin is available in several concentrations containing 100 units/mL (U-100), 200 units/mL (U-200), 300 units/mL (U-300), or 500 units/mL (U-500). The most commonly used insulin concentration is U-100. Concentrated insulins containing more than 100 units/mL may be considered for individuals that require larger doses of insulin to control their diabetes.

The pharmacokinetics and pharmacodynamics of insulin products are characterized by the onset, peak, and duration of appearance and action (see Table 94-7). Absorption of insulin from a subcutaneous depot is dependent on several factors, including source of insulin, concentration of insulin, additives to the insulin preparations (eg, zinc and protamine), blood flow to the area (rubbing of injection area, increased skin temperature, and exercise in muscles near the injection site may enhance absorption), and injection site. The abdomen provides the most consistent absorption for insulin.

TABLE 94-7

Pharmacodynamics of Insulin Preparations

Preparations (U-100 Unless Otherwise Noted)	Onset	Peak[a]	Duration[a]
Ultra-rapid acting			
Insulin aspart (Fiasp)	15-20 min[b]	90-120 min	5-7 hr

Insulin lispro aabc (Lyumjev)	15-17 min[c]	120-174 min	4.6-7.3 hr
Insulin human—inhaled (Afrezza)	12 min	35-55 min	1.5-4.5 hr
Rapid-acting			
Insulin aspart (NovoLog)	10-20 min	30-90 min	3-5 hr
Insulin lispro U-100, U-200 (Humalog, Admelog)			
Insulin glulisine (Apidra)			
Short-acting			
Regular (Humulin R, Novolin R)	30-60 min	2-4 hr	5-8 hr
Intermediate-acting			
NPH (Humulin N, Novolin N)	2-4 hr	4-10 hr	10-24 hr
Regular U-500 (Humulin R 500)	15-30 min	4-8 hr	13-24 hr
Long-acting			
Insulin detemir (Levemir)	1.5-4 hr	6-14[d] hr	16-20 hr
Insulin glargine (Lantus, Basaglar)	2-4 hr	No peak	20-24 hr
Insulin glargine U-300 (Toujeo)	6 hr	No peak	36 hr
Insulin degludec U-100, U-200 (Tresiba)	1 hr	No peak	42 hr
Combination Products			
70% NPH/30% Regular (Humulin 70/30, Novolin 70/30)	30-60 min	Dual	10-16 hr
75% NPL, 25% lispro (Humalog 75/25)	5-15 min		10-16 hr
50% NPL, 50% lispro (Humalog 50/50)	5-15 min		10-16 hr
70% insulin aspart protamine, 30% insulin aspart (Novolog 70/30)	5-15 min		15-18 hr

NPH, neutral protamine Hagedorn; NPL, insulin lispro protamine suspension.

[a] The peak and duration of insulin action are variable, depending on the injection site, duration of diabetes, kidney function, smoking status, and other factors.

[b] Onset of appearance is 2.5 minutes compared to 5.2 minutes for insulin aspart (NovoLog).

[c] Onset of appearance is 1 minute

[d] Long-acting insulins are considered "peakless," although they have exhibited peak effects during comparative testing.

Basal insulin, also called background insulin, refers to longer-acting insulins that regulate BG levels in between meals by suppressing hepatic glucose production and maintaining near-normal glycemic levels in the fasting state. Bolus insulin refers to short- or rapid-acting insulins that cover meals (also called prandial insulin) or glycemic excursions (also called correction insulin). Basal insulin is the preferred and most convenient initial insulin formulation in patients with type 2 DM while patients with type 1 DM require a combination of basal and bolus insulin to achieve adequate glycemic control.[31,32]

Basal insulin options include NPH, detemir, glargine U-100, glargine U-300, degludec U-100, or degludec U-200. From a pharmacokinetic/pharmacodynamic (PK/PD) perspective, NPH is the least ideal basal insulin as it has a distinct peak and a duration of action much less than 24 hours. While it can be given once daily in some patients with type 2 DM, it usually is dosed twice daily. Detemir also has a peak and often lasts less than 24 hours, but has a more ideal profile compared to NPH. It can be given once daily in some patients but should be dosed twice daily when low doses (less than 0.3 units/kg) are used. Insulin glargine U-100 offers a slightly better profile; it is considered to be peakless and can usually be given once daily. The longer-acting agents (glargine U-300 and degludec) have no peak and a longer duration of action compared to glargine U-100 and detemir. They are given once daily. It is important to consider whether these PK/PD differences translate into clinically meaningful differences in patient outcomes. Clinical trial evidence indicates that all basal insulins can achieve similar A1C reductions if dosed and titrated properly; but the longer-acting basal insulins have a lower risk of hypoglycemia, particularly nocturnal hypoglycemia, and may result in less glucose variability. They do however cost more, so the benefits and risks need to be considered on a patient-specific level.

Bolus insulin options include short-acting regular, rapid-acting insulins (aspart, lispro, and glulisine), and ultra-rapid insulins (inhaled human insulin, fast-acting insulin aspart [Fiasp], and insulin lispro aabc [Lyumjev]). Similar to basal insulins, the PK/PD profiles of bolus insulins have improved over time with the rapid-acting insulins offering a faster onset and shorter duration of action compared to regular insulin and the ultra-rapid insulins offering an even faster onset. Rapid and ultra-rapid acting agents may more closely mimic prandial endogenous insulin release. This is likely more relevant to patients with type 1 DM, where therapy is aiming to mimic a functioning pancreas that secretes insulin rapidly after a meal. Rapid-acting insulins have a modestly lower risk of hypoglycemia compared to regular insulin; however, efficacy can be achieved with all prandial insulins and the differences in cost can be substantial. Therefore, when selecting a bolus insulin, a patient-specific evaluation of the benefits and risks should be done.[31,32]

U-500 regular insulin is reserved for use in patients with extreme insulin resistance. It is most often given two or three times a day. To avoid medication errors, it is recommended to prescribe U-500 regular in a pen device or to use U-500 syringes if dispensing U-500 regular in a vial.

Various premixed insulin products, which contain both a basal and a prandial component, are also available and can offer an alternative for patients who require fewer injections or a simpler regimen. However, these products are limited by their fixed mixed formulations which can make tailoring the dosing regimen challenging.

Although endogenous hyperinsulinemia and insulin resistance have been associated with increased CV risk, exogenous insulin therapy has not been associated with increased adverse CV outcomes in several large-scale clinical trials.[17,20,33]

The most common adverse effect reported with insulin is hypoglycemia. It is more common in patients on intensive insulin therapy regimens. Patients with type 1 DM experience more hypoglycemic events when compared to type 2 DM patients who use insulin. In the UKPDS study, the percentage of type 2 DM patients who needed third-party assistance due to a severe hypoglycemic reaction was 2.3%.[20] In the DCCT study, intensive glycemic control increased the risk of severe hypoglycemia threefold when compared to conventional therapy in patients with type 1 DM.[17] Insulin use is associated with an increased risk of hospitalizations in older adults based on public health surveillance data.[34]

Insulin also causes dose-dependent weight gain, which predominantly occurs in truncal fat. Weight gain can be minimized by using physiologic insulin replacement strategies or combining insulin therapy with other medications that mitigate weight gain or promote weight loss.

Insulin can cause injection site reactions including redness, pain, itching, urticaria, edema, and inflammation. Administration of insulin subcutaneously can result in lipoatrophy (depression in the skin) or lipohypertrophy (enlargement or thickening of tissue) in some patients. Lipohypertrophy is caused by repeated injections into the same injection site. Due to insulin's anabolic actions, fat accumulates at the injection site and absorption at this site becomes variable. Lipoatrophy, in contrast, is due to insulin antibodies or allergic-type reactions that destroy the fat at the site of injection. Routinely rotating injection sites prevents these problems from developing and, when lipodystrophy is detected, the injection site should be avoided.

Concerns have been raised about a potential risk of cancer with insulin glargine, but trial results have been conflicting. While some studies using administrative data have found an association between insulin glargine and cancer, other meta-analyses and prospective studies have not.[33]

Inhaled human insulin can cause cough and upper respiratory infections and its use in chronic obstructive pulmonary disease and asthma is contraindicated due to bronchospasm risk. Inhaled insulin use has been associated with a small decline in pulmonary function and patients should have spirometry tests performed at baseline, 6 months, and annually thereafter. If a 20% reduction or greater in forced expiratory volume in 1 second is observed, inhaled insulin should be discontinued.

Insulin is degraded in the liver, muscle, and kidney. Liver deactivation is 20% to 50% in a single passage through the liver. Approximately 15% to 20% of insulin metabolism occurs in the kidney. This may explain the lower insulin dosage requirements and longer duration of activity observed in patients with ESKD.

The dose of insulin must be individualized. In type 1 DM, the average daily requirement for insulin is 0.5 to 0.6 units/kg, with approximately 50% being delivered as basal insulin, and the remaining 50% dedicated to meal coverage. During the honeymoon phase, it may fall to 0.1 to 0.4 units/kg. During acute illness or with ketosis or states of relative insulin resistance, the need for higher dosages is common. In type 2 DM, a higher dosage is required for those patients with significant insulin resistance. Dosages vary widely depending on the degree of insulin resistance and concomitant antihyperglycemic medication use. More specific information on insulin dosing is included in the “General Approach to Hyperglycemia Management” section.

The effectiveness of insulin is highly dependent on its appropriate use. Product selection, education and training, and reinforcement are crucial. Counseling must include proper administration (including dose, injection technique, and timing of injection), glycemic targets, SMBG, dose titration or adjustment, storage, and prevention, detection, and treatment of hypoglycemia. Each insulin product is unique in the delivery device used. Some insulin products are available in vials, disposable pen devices, or pen cartridges, but many newer insulins are only available in pen devices. Each pen device product has different quantities, maximum injection doses, storage requirements, and expirations. NPH insulin and all suspension-based insulin preparations should be inverted or rolled gently at least 20 times to fully suspend the insulin prior to each use. Improper mixing of the suspension prior to administration can lead to glycemic variability. Pharmacists should review recent guidelines on proper injection technique and prescribing information for specific products prior to counseling patients and utilize reliable, up-to-date patient education resources to ensure product-specific, accurate counseling information.[35,36]

Biguanides

Metformin is the only biguanide available in the United States. It is oral and available as an immediate-release formulation that is dosed twice daily or an extended-release (XR) formulation that is dosed once or twice daily (Table 94-8). Its benefits in relation to glucose-lowering are complex and not yet fully understood. At the cellular level, metformin activates AMP kinase. Metformin has been shown to decrease hepatic glucose production, yet not all of its effects can be explained by that mechanism and there is increasing evidence of mechanisms in the gut. Additionally, metformin's effects may be partially related to enhanced insulin sensitivity in peripheral (muscle) tissues, which allows for an increased uptake of glucose into muscle cells. Metformin has no direct effect on the β-cell, but insulin concentrations are reduced due to improved insulin sensitivity.[37]

TABLE 94-8

Dosing Recommendations for Oral Medications Used to Treat Type 2 Diabetes

Generic Name	Starting Dose	Usual Recommended Dose	Maximal dose (mg/day)	Dosing/Use based on Kidney Function[a]
Biguanides				
Metformin	500 mg once or twice daily or 850 mg once daily, titrate to target dose as tolerated	1,000 mg twice daily	2,550	Do not initiate if eGFR 30-45; Do not use if eGFR<30
Metformin XR	500 mg to 1,000 mg once daily, titrate to target dose as tolerated	2,000 mg once daily	2,500	Do not initiate if eGFR 30-45; Do not use if eGFR<30
Sodium-glucose co-transporter (SGLT)-2 inhibitors				
Canagliflozin	100 mg once daily	100-300 mg once daily	300	100 mg once daily if eGFR 30-60; Do not initiate if eGFR < 30
Dapagliflozin	5 mg once daily[b]	5-10 mg once daily	10	Not recommended for glycemic control if eGFR < 45[c]; Do not initiate if eGFR < 25
Empagliflozin	10 mg once daily	10-25 mg once daily	25	Not recommended if eGFR < 45
Ertugliflozin	5 mg once daily	5-15 mg once daily	15	Do not initiate if eGFR < 60; Do not use if eGFR < 30
Dipeptidyl peptidase (DPP)-4 inhibitors				
Alogliptin	25 mg once daily	25 mg once daily	25	12.5 mg once daily if CrCl 30-60 mL/min (0.5-1.0 mL/s); 6.25 mg once daily if CrCl < 30 mL/min (0.5 mL/s)
Linagliptin	5 mg once daily	5 mg once daily	5	No dose adjustment needed
Saxagliptin	2.5-5 mg once daily	5 mg once daily	5	2.5 mg once daily if eGFR≤50
Sitagliptin	100 mg once daily	100 mg once daily	100	50 mg once daily if eGFR 30-50 25 mg once daily if eGFR<30
Thiazolidinediones (TZD)				
Pioglitazone	15 mg once daily	30 mg once daily	45	No dose adjustment required

Rosiglitazone	4 mg once daily or in two divided doses	4 mg once daily or in two divided doses	8	No dose adjustment required
Sulfonylureas (first generation)				
Chlorpropamide	250 mg once daily (100 mg once daily in older adults)	100-500 mg once daily	750	Consider alternative agent or initiate conservatively at 100 mg in kidney insufficiency to avoid hypoglycemia
Tolazamide	250 mg once daily (100 mg once daily in older adults or if FPG < 200 mg/dL [11.1 mmol/L])	250-500 mg once daily	1,000	Consider alternative agent or initiate conservatively at 100 mg in kidney insufficiency to avoid hypoglycemia
Tolbutamide	1,000-2,000 mg once daily (250-500 mg once daily in older adults)	1,000-2,000 mg once daily	3,000	Consider alternative agent or initiate conservatively in kidney insufficiency to avoid hypoglycemia
Sulfonylureas (second generation)				
Glimepiride	1-2 mg once daily (1 mg once daily in older adults)	4 mg once daily	8	Initiate conservatively at 1 mg in kidney insufficiency to avoid hypoglycemia
Glipizide	5 mg once daily (2.5 mg daily in older adults)	5-10 mg once daily	40	Initiate conservatively at 2.5 mg in kidney insufficiency to avoid hypoglycemia
Glipizide XL	5 mg once daily (2.5 mg once daily in older adults)	5-10 mg once daily	20	Initiate conservatively at 2.5 mg in kidney insufficiency to avoid hypoglycemia
Glyburide	2.5-5 mg once daily (1.25 mg once daily in older adults)	5-10 mg once daily	20	Consider alternative agent or initiate conservatively at 1.25 mg in kidney insufficiency to avoid hypoglycemia
Glyburide micronized	1.5-3 mg once daily (0.75 mg once daily in older adults)	3-6 mg once daily	12	Consider alternative agent or initiate conservatively at 0.75 mg in kidney insufficiency to avoid hypoglycemia
Meglitinides				
Nateglinide	120 mg three times daily before meals	120 mg three times daily before meals	360	No adjustment required
Repaglinide	1-2 mg three times daily before meals (0.5 mg before meals if A1C<8% [0.08; 64 mmol/mol])	2-4 mg three times daily before meals	16	Initiate conservatively at 0.5 mg before meals if CrCl 20-40 mL/min (0.33 to 0.67 mL/s)

α-Glucosidase inhibitors				
Acarbose	25 mg once to three times daily with meals	50 mg once to three times daily with meals	300	Avoid if CrCl < 25 mL/min (0.42 mL/s)
Miglitol	25 mg once to three times daily with meals	50 mg once to three times daily with meals	300	Avoid if CrCl < 25 mL/min (0.42 mL/s)
Bile acid sequestrants				
Colesevelam	1.875 g twice daily or 3.75 g once daily	1.875 g twice daily or 3.75 g once daily	3.75 g/day	No dose adjustment needed
Dopamine agonists				
Bromocriptine	0.8 mg once daily	1.6-4.8 mg once daily	4.8	No dose adjustment needed

[a] eGFR units: mL/min/1.73 m^2

[b] For indications other than glycemic control; the recommended starting dose is 10 mg.

[c] For indications other than glycemic control: 10 mg for eGFR>25; if eGFR < 25 patients may continue until dialysis but initiation is not recommended.

Metformin is generally the initial drug of choice for glucose lowering in patients with type 2 DM due to extensive experience, high efficacy, minimal hypoglycemia risk, positive or neutral effects on weight, potential positive impact on CV risk, manageable side-effect profile, and low cost. Current treatment guidelines recommend initiating metformin as first-line pharmacotherapy unless a contraindication or intolerability exists.[31,32] Metformin consistently reduces A1C levels by 1.5% to 2.0% (0.015 and 0.020; 16 and 22 mmol/mol) and FPG levels by 60 to 80 mg/dL (3.3-4.4 mmol/L) in drug naïve patients with A1C values of approximately 9% (0.09; 75 mmol/mol). Metformin does not cause weight gain, and may actually lead to a modest (2-3 kg) weight loss. Since metformin does not directly increase insulin secretion from the pancreas, it has a low risk of hypoglycemia. Metformin also has positive effects on several components of the insulin resistance syndrome. Metformin decreases plasma triglycerides and low-density lipoprotein cholesterol (LDL-C) by approximately 8% to 15% and modestly increases high-density lipoprotein cholesterol (HDL-C) by 2%.

Metformin reduced the composite of all diabetes-related endpoints by 32%, diabetes-related death by 42%, and all-cause mortality by 36% in overweight subjects in the UKPDS compared to conventional treatment. Intensive treatment with metformin was also significantly better than intensive treatment with sulfonylureas or insulin at reducing any diabetes-related endpoint, all-cause mortality, and stroke. However, meta-analyses have not confirmed these benefits.[21,38,39] Metformin frequently causes GI side effects, including diarrhea, abdominal discomfort, and/or stomach upset. These side effects are usually dose-dependent, transient, mild in nature, and can be minimized with slow dose titration. Patients should take metformin with or immediately after meals. When initiating therapy, it is important to use a low dose, typically 500 mg given with the largest meal, to minimize GI adverse effects. The dose is then increased in 500 mg increments over several weeks. Approximately 5% to 10% of patients cannot tolerate metformin despite the slow dose titration. Extended-release metformin may lessen some of the GI side effects, but a recent head-to-head comparison of immediate-release versus extended-release metformin found no significant differences in rates of GI adverse effects.[40]

Metformin may cause a metallic taste, due to metformin in salivary secretions and may lower vitamin B_{12} concentrations. Therefore, B_{12} levels or methylmalonic acid should be measured annually or if a deficiency is suspected. Peripheral neuropathy, a microvascular complication that is common in diabetes, could manifest or worsen with B_{12} deficiency. Vitamin B_{12} supplementation by sublingual, oral, or injection easily treats this deficiency.

Rare cases of lactic acidosis have been reported with metformin, usually in the setting of severe illness or acute kidney injury. The risk appears to be exceedingly small but may increase in patients with moderate-to-severe kidney insufficiency or tissue hypoperfusion states such as acute congestive heart failure, excessive alcohol intake, and hepatic impairment. The clinical presentation of lactic acidosis is often nonspecific flu-like symptoms. The diagnosis is therefore made by laboratory confirmation of high lactic acid levels and acidosis.

Metformin can be used in combination with any other antihyperglycemic therapy and is often continued when insulin therapy is initiated. The target dose for metformin is 1,000 mg twice daily or 2,000 mg daily if the extended-release product is used. The minimal effective dose of metformin is 1,000 mg/day (Table 94-8). Approximately 80% of the glycemic-lowering effect may be seen at 1,500 mg daily.

Metformin is renally excreted and accumulates in patients with kidney insufficiency; therefore, metformin is contraindicated in patients with an eGFR <30 mL/min/1.73 m^2 and should be used with caution in patients with milder kidney insufficiency. Initiation of metformin is not recommended in patients with an eGFR 30 to 45 mL/min/1.73 m^2 but can be continued with increased kidney function monitoring; a dose reduction of 50% of maximal dose may be warranted.[41-43] Due to the risk of acute kidney failure when IV contrast dye is used during imaging procedures, metformin therapy should be withheld starting the day of the procedure and resumed 2 to 3 days later, if normal kidney function has been documented. It need not be withheld for days prior to the procedure.

Sodium-Glucose Co-transporter-2 Inhibitors

Four SGLT-2 inhibitors have been approved by the FDA including canagliflozin, dapagliflozin, empagliflozin, and ertugliflozin, all of which are oral, once-daily products. SGLT-2 inhibitors reduce plasma glucose by preventing the kidneys from reabsorbing glucose back into the bloodstream, leading to increased glucose excretion in the urine. By inhibiting SGLT-2, the renal tubular threshold for glucose reabsorption is lowered and glucosuria occurs at lower levels of plasma glucose concentrations. SGLT-2 inhibition lowers BG through an insulin-independent mechanism and exerts its glucose-lowering effect whenever the plasma glucose is elevated. Thus, SGLT-2 inhibitors can lower both FPG and PPG and are effective even in the absolute absence of insulin. Although SGLT-2 inhibitors block the reabsorption of 90% of the filtered glucose load, which could theoretically result in up to 170-g loss of glucose/day in the urine, urinary glucose excretion (UGE) does not exceed 75 to 85 g/day, because SGLT-1 begins to compensate and can reabsorb up to 30% to 40% of the filtered glucose load, when working at maximal capacity. Thus, when SGLT-2 is inhibited, SGLT-1 instantaneously can augment its reabsorption of glucose and blunt the glucosuric effect of the SGLT-2 inhibitor.

The SGLT-2 inhibitors are considered to have intermediate A1C lowering efficacy and reduce A1C by 0.5% to 1% (0.005 to 0.01; 6 to 11 mmol/mol). They appear to be more efficacious in patients with higher baseline A1C levels. As eGFR declines, the amount of glucose that reaches the proximal tubule declines; thus, kidney impairment decreases the glucose-lowering efficacy of SGLT-2 inhibitors. Increased UGE leads to the loss of 200 to 300 kcal/day (840 to 1300 kJ/day), which may contribute to 1 to 5 kg of weight loss. The filtering of more glucose in the urine also causes an osmotic diuresis effect that can result in modest reductions in systolic BP by 3 to 4 mm Hg and diastolic BP by 1 to 2 mm Hg. Because of the insulin-independent mechanism, SGLT-2 inhibitors are unlikely to cause hypoglycemia unless combined with medications such as sulfonylureas, meglitinides, or insulin.

The SGLT-2 inhibitors have additional benefits related to improving CV, HF, and CKD outcomes. Large-scale, CV outcome trials have been completed for empagliflozin, canagliflozin, and dapagliflozin. Both empagliflozin and canagliflozin demonstrated benefit at reducing major adverse CV events (myocardial infarction, stroke, or CV death) in patients with type 2 DM and established CVD or high CV risk.[44-46] Secondary endpoints of HF hospitalizations and worsening nephropathy were also reduced in these studies. Dapagliflozin was noninferior (but not superior) to placebo at reducing major adverse CV events in patients with type 2 DM who had or were at risk for ASCVD. There was a significant reduction in the composite endpoint of heart failure hospitalizations or CV death with dapagliflozin compared to placebo, and a reduction in the progression of kidney disease.[47] Additional outcome trials have provided primary outcomes evidence demonstrating a significant benefit from dapagliflozin and empagliflozin at reducing the risk of worsening heart failure or CV death in patients with heart failure, with or without type 2 DM[48,49] and the benefit from dapagliflozin at reducing the risk of adverse kidney-related outcomes in patients with CKD with or without type 2 DM.[50] There is also primary outcome evidence demonstrating kidney benefit of canagliflozin in patients with CKD and type 2 DM.[51,52] Due to these benefits, the SGLT-2 inhibitors have expanded FDA indications beyond glucose-lowering (Table 94-9).

TABLE 94-9

SGLT-2 Inhibitors and GLP-1 Receptor Agonists with FDA Indications Beyond Glycemic Control[a]

Drug Name	FDA Indications Beyond Glycemic Control
SGLT-2 inhibitors	
Canagliflozin	• to reduce the risk of major adverse CV events in adults with type 2 DM and established CVD • to reduce the risk of ESKD, doubling of serum creatinine, CV death, and hospitalization for HF in adults with type 2 DM and diabetic nephropathy with albuminuria
Dapagliflozin	• to reduce the risk of hospitalization for HF in adults with type 2 DM and either established CVD or multiple CV risk factors • to reduce the risk of CV death and hospitalization for HF in adults with HF with reduced ejection fraction (NYHA class II-IV) • to reduce the risk of sustained eGFR decline, ESKD, CV death and hospitalization for HF in adults with CKD at risk of progression
Empagliflozin	• to reduce the risk of CV death in adult patients with type 2 DM and established CVD • to reduce the risk of CV death and hospitalization for heart failure in adults with heart failure
GLP-1 receptor agonists	
Dulaglutide	• to reduce the risk of major adverse CV events in adults with type 2 DM who have established CVD or multiple CV risk factors
Liraglutide	• to reduce the risk of major CV events such as heart attack, stroke, or death in adults with type 2 DM with known heart disease
Semaglutide (SC)	• to reduce the risk of major adverse CV events (CV death, nonfatal myocardial infarction or nonfatal stroke) in adults with type 2 DM and established CVD

[a] liraglutide and semaglutide (SC) are also indicated for weight loss under different brand names at higher doses

For glycemic control, the SGLT-2 inhibitors can be added to metformin or used in combination with other second-line agents. They can be used as monotherapy in patients who cannot tolerate or take metformin. They are recommended by the ADA guidelines for many patient populations including those with indicators of high risk or established ASCVD, HF, or CKD. For patients with those comorbidities, SGLT-2 inhibitors should be considered independently of baseline A1C, individualized A1C target, or metformin use. The SGLT-2 inhibitors are also recommended for those with a compelling need to avoid hypoglycemia or a compelling need to avoid weight gain or induce weight loss.

Excess glucose in the urine is responsible for causing genital mycotic infections, the most common side effect of the SGLT-2 inhibitors. There is also a slightly increased risk of urinary tract infections. Genitourinary (GU) infections occur more frequently in women and uncircumcised men. In clinical trials, GU infections led to discontinuation in less than 1% of patients; most GU infections were treated and patients were able to continue the SGLT-2 therapy. Patients should be educated about the signs and symptoms of GU infections and the importance of proper personal hygiene.

SGLT-2 inhibitors can also cause polyuria, dehydration, dizziness, or hypotension due to the osmotic diuresis effects. Symptomatic hypotension may occur more frequently in patients with low baseline BP or an eGFR less than 60 mL/min/1.73 m^2. Concomitant diuretic use may increase the risk of orthostatic hypotension and electrolyte abnormalities. Patients should be monitored carefully and dose or drug therapy adjustments may be needed. Older adults and patients with stage 4 or 5 CKD are not optimal candidates for SGLT-2 inhibitors. Older adults typically have diminished kidney function and, because they may have poor thirst response, they are predisposed to dehydration. The mechanism of action and osmotic diuresis with SGLT-2 inhibitors may affect several laboratory tests. LDL-C and HDL-C increase slightly with SGLT-2 inhibitors. Hemoconcentration from diuresis can result in a 2% to 3% increase in hematocrit. Urinalysis will always be positive for glucose due to the mechanism of action.

Other safety concerns that have been raised since SGLT-2 inhibitors have come to market include ketoacidosis, amputations, fractures, and Fournier gangrene. Several cases of ketoacidosis have been reported and meta-analyses have shown a small increased risk, although absolute numbers are small. Unlike the typical presentation of DKA, SGLT-2 inhibitor-related ketoacidosis presents uniquely, in that glucose levels typically do not go over 250 mg/dL (13.9 mmol/L) because of the increased UGE. Most cases have been in patients with type 1 DM, thus the SGLT-2 inhibitors are not currently approved by the FDA in this population. Insulin-deficient patients (those with type 1 DM, LADA, or insulin-requiring type 2 DM) are at the highest risk, especially in the setting of decreased insulin use, increased insulin needs (acute illness or infection, surgery, trauma), or low-carbohydrate intake or dehydration. Patients should be well hydrated prior to treatment initiation, temporarily stop the drug if a serious illness is encountered, and should not decrease the insulin dose prospectively when it is initiated.

Canagliflozin was associated with an increased risk of bone fracture and lower-limb amputations in its large CV outcome trial. Many of the fractures were distal fractures of the upper extremities after a fall, and thus may be related to dizziness and orthostatic hypotension. Amputations are more common in patients with peripheral neuropathy, peripheral vascular disease, or prior amputations, so caution should be used in this patient population when considering SGLT-2 inhibitor therapy.

The use of SGLT-2 inhibitors has been associated with Fournier gangrene, a rare urological emergency characterized by necrotizing infection of the external genitalia, perineum, and perianal region. To date, 55 cases have been reported and, thus, causality has not been established.[53]

The SGLT-2 inhibitors should be initiated at a low dose. Volume status, adverse effects, and kidney function should be assessed. The dose may be titrated in patients who are tolerating the drug well and require additional glucose control. Since the glucose-lowering effect of these medications is dependent on kidney function, it is not recommended to start or continue SGLT-2 therapy for the purpose of glucose-lowering when the eGFR is consistently less than 45 mL/min/1.73 m^2, although these medications can be used for alternative indications at lower eGFR levels. Use and dose recommendations vary between agents for patients with kidney dysfunction (Table 94-8).

Glucagon-Like Peptide-1 Receptor Agonists

Currently, seven GLP-1 RAs are available in the United States. Six of these are delivered subcutaneously with dosing schedules ranging from twice daily to once weekly and one is delivered orally once daily (Table 94-10). The class mimics the action of endogenous GLP-1. They stimulate insulin secretion from pancreatic β-cells in a glucose-dependent manner. In addition, during hyperglycemia, GLP-1 RAs reduce inappropriately elevated levels of glucagon, which results in decreased hepatic glucose output. These agents also have a direct effect on the stomach through the autonomic nervous system to slow gastric emptying, thereby reducing meal-related glucose excursions. Additionally, agents that penetrate the blood-brain barrier increase satiety via the central nervous system. These actions result in a reduction in both glucose and weight. GLP-1 RAs also potentially preserve pancreatic β-cell function and protect against cytokine-induced apoptosis. All GLP1 RAs result in pharmacologic levels of GLP-1 activity and are resistant to the rapid degradation by the dipeptidyl peptidase 4 (DPP-4) enzyme.

TABLE 94-10

Clinical Comparisons of GLP-1 Receptor Agonists

Generic Name	Primary Glucose Profile Target	Dose/Route	Interval	Dose/Use Based on Kidney Function	Availability, Storage, Preparation
Exenatide	PPG	5-10 mcg SC	Twice daily (within 60 minutes before breakfast and dinner)	Avoid if CrCl[a] <30 (0.5 mL/s); Use caution when initiating or increasing dose if CrCl 30-50 (0.5-0.83 mL/s)	• Multidose pens (5 mcg/dose, 10 mcg/dose, 60 doses per pen) • Pen needles not supplied with pen • Keep refrigerated • After first use, store at room temperature; discard 30 days after first

					use
Lixisenatide	PPG	10-20 mcg SC	Once daily (1 hr before breakfast)	Limited experience in severe kidney impairment; avoid if eGFR < 15[b]	- Multidose pen (10 mcg, 20 mcg, 14 doses per pen) - Pen needles not supplied with pen - Keep refrigerated - After first use, store at room temperature; discard 14 days after first use
Dulaglutide	FPG and PPG	0.75-4.5 mg SC	Once weekly	Use with caution in patients with ESKD	- Single-dose pen (0.75 mg, 1.5 mg, 3.0 mg, 4.5 mg) - Pen needle attached - Keep refrigerated - May store at room temperature for 14 days
Exenatide XR	FPG and PPG	2 mg SC	Once weekly	Limited experience in severe kidney impairment; not recommended if eGFR or CrCl < 30 (0.5 mL/s); Use with caution if CrCl 30-50 (0.5-0.83 mL/s)	- Single-dose pen (2 mg) - Pen needle supplied with pen - Keep refrigerated; may store at room temperature for 4 weeks - Store flat in original packaging, protected from light - Remove from refrigerator 15 minutes prior to mixing - Requires reconstitution; administer dose immediately once reconstituted
Liraglutide	FPG and PPG	0.6-1.8 mg SC	Once daily	Limited experience in ESKD	- Multidose pen (6 mg/mL, 3 mL; each pen delivers doses of 0.6, 1.2, or 1.8 mg) - Pen needles not supplied with pen - Keep refrigerated - After first use, store at room temperature; discard 30 days after first use
Semaglutide	FPG and PPG	0.25-1 mg SC	Once weekly	No dose adjustment recommended	- Multidose pen (low dose pen: 1.34 mg/mL, 2mg/1.5 mL, delivers 0.25 mg or 0.5 mg doses; high-dose pen: 1.34 mg/mL, 4 mg/3 mL, delivers 1 mg dose) - Pen needles supplied with pen - Keep refrigerated - After first use, store at room temperature; discard 56 days after first use

Semaglutide	FPG and PPG	3-14 mg orally	Once daily	No dose adjustment recommended	- Store at room temperature - Should be taken 30 minutes before first food, beverage, or other medication of the day with no more than 4 ounces of water

CrCl, creatinine clearance; eGFR, estimated glomerular filtration rate; ESKD, end-stage kidney disease; FPG, fasting plasma glucose; PPG, postprandial glucose; SC, subcutaneous.

[a]CrCl units: mL/min

[b]eGFR units: mL/min/1.73 m^2

The A1C lowering efficacy with GLP-1 RAs is considered high but depends on baseline glycemic control, background therapy, and the specific agent used. GLP-1 RAs can also lead to weight loss. The average weight loss is about 1-3 kg with GLP-1 RAs but is highly dependent on the specific agent and dose used, with clinical trial results varying from an average 0.3 kg weight gain to as much as a 6.5 kg weight loss.

Currently, available GLP-1 RAs include dulaglutide, exenatide, exenatide XR, lixisenatide, liraglutide, and semaglutide (in both an injectable and oral formulation). Multiple differences exist in the characteristics of the individual agents within the class, including molecular structure and size, half-life, duration of action, ability to penetrate different tissue compartments, and homology to native GLP-1, which, in turn, lead to important clinical differences in efficacy, rates of adverse effects, dosing schedules, and impact on glucose profile (Table 94-10). Short-acting agents (exenatide and lixisenatide) predominantly lower PPG levels, likely due to their effect on gastric emptying. Long-acting agents (dulaglutide, liraglutide, exenatide XR, and semaglutide) lower both FPG and PPG, but demonstrate larger effects on FPG levels, due to their longer half-life and resultant suppression of glucagon overnight. Based on several head-to-head trials comparing specific GLP-1 RAs to each other, dulaglutide, liraglutide, and semaglutide have the highest A1C lowering efficacy while exenatide and lixisenatide have the lowest.[54] Semaglutide appears to have the highest weight loss efficacy, followed by liraglutide, dulaglutide, exenatide, and lixisenatide.[55,56]

The GLP-1 RAs have additional benefits related to improving CV and CKD outcomes. Large-scale CV outcome trials have been completed for dulaglutide, exenatide XR, lixisenatide, liraglutide, and semaglutide (SC). Both lixisenatide and exenatide XR demonstrated CV safety but did not reduce the rate of major adverse CV events (myocardial infarction, stroke, or CV death). Liraglutide, semaglutide, and dulaglutide, however, not only demonstrated CV safety but also demonstrated benefit at reducing the risk of major adverse CV events (myocardial infarction, stroke, or CV death) in patients with type 2 DM and established CVD or high CV risk.[44,57-59] The secondary endpoint of worsening nephropathy was also reduced in these studies. Due to these benefits, the GLP-1 RAs have expanded FDA indications beyond glucose-lowering (Table 94-9).

For glycemic control, the GLP-1 RAs are treatment options at multiple time points in the type 2 DM treatment algorithm and can be used in combination with many other agents including metformin, sulfonylureas, SGLT-2 inhibitors, and basal insulin. They can be used as monotherapy in patients who cannot tolerate or take metformin. They are recommended for many patient populations including those with indicators of high risk or established ASCVD or CKD, and those with a compelling need to avoid hypoglycemia or a compelling need to avoid weight gain or induce weight loss. They should not be used in combination with DPP-4 inhibitors due to the similar mechanisms of action. A significant amount of evidence shows the beneficial effect of the combination of GLP-1 RA and a basal insulin.

The most common adverse effects associated with GLP1-RAs are GI in nature, including nausea, vomiting, and diarrhea. These adverse effects appear to be dose-related so dose titration is recommended. They usually occur early in the treatment course, are typically mild in nature, and transient. Occasionally, the GI side effects are significant enough to require discontinuation. Long-acting preparations tend to have less impact on gastric emptying, and thus a slightly lower risk of nausea, compared to short-acting agents. Patients should be instructed to eat slowly and stop eating when satiated otherwise nausea may worsen or cause vomiting.

GLP-1 RAs enhance insulin secretion in a glucose-dependent manner in response to food intake; thus, the risk of hypoglycemia is low when combined with metformin, DPP-4 inhibitors, SGLT-2 inhibitors, or a TZD. However, when combined with a sulfonylurea or insulin, hypoglycemia may occur.

Antibody formation to GLP-1 RAs may occur, which could potentially attenuate the glycemic-lowering effects. Antibody formation is more likely to occur with exendin-4-based agents (exenatide, exenatide XR, and lixisenatide) than with other agents. Injection site reactions have also been reported in patients taking injectable GLP-1 RAs. These reactions may be more common in patients with high antibody titers. Exenatide XR can also cause injection site nodules, likely due to its formulation. It is encapsulated in microspheres made of a biodegradable polymer, which releases the drug over a sustained time interval. The microspheres can lead to injection site nodules described as pea-sized, hard, subcutaneous, lumps, masses, or induration. Hypersensitivity reactions, including anaphylaxis and angioedema, have also been reported with most GLP-1 RAs.

GLP-1 RAs have been associated with cases of acute pancreatitis, but no causal relationship has been established. While additional study is needed, it should be noted that (1) patients with type 2 DM are at inherently higher risk for developing pancreatitis; (2) GLP-1 RAs may mask the initial signs of pancreatitis, including nausea, vomiting, and abdominal pain; and (3) large studies have not linked GLP-1 RA use to a higher incidence of acute pancreatitis. In a patient with a history of pancreatitis, the benefits must be weighed against the potential risks. A GLP-1 RA should not be used in patients with chronic pancreatitis. If a patient reports abdominal pain, nausea, and repeated vomiting, it is best to discontinue therapy temporarily and confirm that the symptoms are not a sign of a more serious underlying problem. GLP-1 RAs have not been studied in patients with gastroparesis, but since they delay gastric emptying they are not recommended in this patient population.

Long-acting GLP-1 RAs are contraindicated in patients with a history of medullary thyroid carcinoma or multiple endocrine neoplasia type 2 due to a risk of medullary thyroid carcinoma. This contraindication is based on rodent model data that reported a higher risk of C-cell tumors of the thyroid but has not been seen in humans. Rodents may not be the ideal model to study this effect as they express a high number of GLP-1 receptors on thyroid C-cells. The expression of GLP-1 receptors in the thyroid of humans is minimal. Rodents also have a higher baseline prevalence of C-cell tumors compared to humans. There is no contraindication in patients with a history of other types of thyroid cancers.

Most GLP-1 RAs require subcutaneous administration into the abdomen, thigh, or upper arm. Each agent uses a unique injection pen device with unique administration requirements; patients must be instructed on how to use the specific product they have been prescribed. The short-acting agents have specific timing requirements in relation to meals since their mechanisms are more targeted toward slowing gastric emptying postprandially. If the dose of exenatide or lixisenatide is missed, it should not be taken after the meal. The long-acting agents have more flexibility with the timing of doses and can be taken at any time of day, with or without food. Oral semaglutide should be taken 30 minutes before the first food, beverage, or other medication of the day with no more than 4 ounces of water. Most of the GLP-1 RAs (except for exenatide XR) have recommended lower doses when initiating the drug, followed by titration to higher doses if needed for glycemic control. This is to minimize GI adverse effects since the GI adverse effects are dose-related and transient. For the once-weekly agents, steady state is attained at 6 to 8 weeks. For GLP-1 RAs administered weekly, if a dose is missed it should be taken as soon as possible but not within 3 days of the next dose. Use caution when starting or increasing the dose of GLP-1 RAs in patients with kidney insufficiency as there have been case reports of acute kidney injury or worsening kidney function. Most occurred in patients who experienced nausea, vomiting, diarrhea, or dehydration. Exenatide and exenatide XR should be avoided in patients with eGFR<30 mL/min/1.73 m^2, and lixisenatide should be avoided in patients with eGFR < 15 mL/min/1.73 m^2.

Dipeptidyl Peptidase-4 Inhibitors

Four DPP-4 inhibitors are approved by the FDA: sitagliptin, saxagliptin, linagliptin, and alogliptin, all of which are oral, once-daily products. These agents inhibit the DPP-4 enzyme responsible for the rapid degradation of GLP-1 and GIP, thereby prolonging the half-life of endogenously produced GLP-1 and GIP. Levels of GLP-1 are deficient in patients with type 2 DM. As these agents block nearly 100% of the DPP-4 enzyme activity for at least 12 hours, normal physiologic, GLP-1 levels are achieved. This leads to an increase in glucose-dependent insulin secretion from the pancreas and a reduction in inappropriate postprandial glucagon secretion, resulting in lower glucose levels without an increase in hypoglycemia when used as monotherapy. These drugs do not alter gastric emptying and do not cause nausea or have significant effects on satiety. DPP-4 inhibitors have a neutral impact on weight.

The DPP-4 inhibitors have moderate glucose-lowering efficacy, with an average reduction in A1C of 0.5% to 0.9% (0.005-0.009; 6-10 mmol/mol) when used at maximum doses. DPP-4 inhibitors have a shallow dose-response curve. There are no clear differences in efficacy between medications within the class. DPP-4 inhibitors are considered second- or third-line therapy in the ADA algorithm, particularly when there is a compelling need to minimize hypoglycemia or weight gain, but they have less A1C-lowering efficacy compared to other medication classes. Potential advantages of the DPP-4 inhibitors include once-daily dosing, oral administration, weight neutrality, low risk of hypoglycemia, and good tolerability. They may be used in older adults with moderate-to-severe kidney insufficiency or those where drug tolerability is a priority. However, their ability to lower BG is modest and they are expensive.

The DPP-4 inhibitors are extremely well-tolerated. Adverse effects are uncommon but could include stuffy, runny nose; headache; or upper respiratory tract infections. Safety concerns that have arisen post-market with the DPP-4 inhibitors include heart failure, pancreatitis, and joint pain. The CV outcome trials with saxagliptin, sitagliptin, linagliptin, and alogliptin all demonstrated the overall CV safety of these agents, with no significant differences in major CV outcomes compared with placebo.[44] However, an increased risk of heart failure hospitalizations with saxagliptin compared with placebo reached statistical significance, and there was a trend toward increased heart failure hospitalizations with alogliptin compared with placebo.[44,60] Because of these findings, prescribing information for both saxagliptin and alogliptin includes information about the increased risk of hospitalization for heart failure, particularly in patients with existing heart or kidney disease. Patients taking these medications should contact their health professional if they develop signs and symptoms of heart failure, and providers should consider discontinuing the medication in patients who develop heart failure.

The FDA has also issued a warning on the risk of severe joint pain with DPP-4 inhibitors. This warning was based on 33 cases between 2006 and 2013. The joint pain occurred between 1 day to years after initial use, and symptoms were relieved after discontinuation of the DPP-4 inhibitor. Patients should not stop taking the drug if symptoms occur but should contact their health professional.

Similar to the GLP-1 RA class, there have been reports of increased risk of pancreatitis with DPP-4 inhibitors, but a causal relationship has not been established and individual, large, prospective studies have not shown an increased risk. A meta-analysis did show a small but statistically significant increased risk of pancreatitis with DPP-4 inhibitor use compared with placebo showing one to two cases of acute pancreatitis for every 1,000 patients treated for 2 years. Thus, pancreatitis appears to be an established yet rare safety concern with these agents.[61] Patients should be informed of the risk and appropriate monitoring should occur if a patient develops signs or symptoms of pancreatitis while taking a DPP-4 inhibitor.

DPP-4 plays an important role in T-cell activation. Theoretically, the inhibition of DPP-4 could be associated with adverse immunologic reactions. To date, however, there has been no evidence of clinically relevant changes in immune function.

There is no need to titrate the dose of DPP-4 inhibitors; however, dose adjustments for kidney function are required for alogliptin, saxagliptin, or sitagliptin (Table 94-8).

Thiazolidinediones

Pioglitazone and rosiglitazone are the two currently FDA-approved TZDs for the treatment of type 2 DM. They are oral agents, dosed once daily (Table 94-8). TZDs work by binding to the peroxisome proliferator activator receptor-γ (PPAR-γ), a nuclear receptor that is predominantly located on fat cells and vascular cells. Activation of PPAR-γ alters the transcription of several genes involved in glucose and lipid metabolism and energy balance. TZDs enhance insulin sensitivity at muscle, liver, and fat tissues. TZDs cause preadipocytes to differentiate into mature fat cells in subcutaneous fat stores. Small fat cells are more sensitive to insulin and more able to store FFAs. This allows a flux of FFAs out of the plasma, visceral fat, and liver into subcutaneous fat, a less insulin-resistant storage tissue. Muscle intracellular fat products, which contribute to insulin resistance, also decline. TZDs also affect adipokines (eg, angiotensinogen, tissue necrosis factor-α, interleukin 6, PAI-1), which can positively affect insulin sensitivity, endothelial function, and inflammation. Of particular note, adiponectin is reduced with obesity and diabetes, but is increased with TZD therapy, which improves endothelial function, insulin sensitivity, and has a potent anti-inflammatory effect.[62]

TZDs are considered second- or third-line agents and can be used in combination with metformin and other commonly prescribed medications for type 2 DM. TZDs have high glycemic-lowering efficacy and reduce A1C values approximately 1.0% to 1.5% (0.010-0.015; 11-22 mmol/mol), FPG levels by 60 to 70 mg/dL (3.3-3.9 mmol/L) at maximal doses, and they have high durability over time. Glycemic-lowering onset is slow and maximal effects may not be seen until 3 to 4 months of therapy. It is important to inform patients of this fact and that they should not stop therapy even if minimal changes in BG levels are initially seen. Pioglitazone consistently decreases plasma triglyceride levels by 10% to 20%, whereas rosiglitazone tends to have a neutral effect. LDL-C concentrations tend to increase with rosiglitazone 5% to 15%, but do not significantly increase with pioglitazone. Both appear to convert small, dense LDL particles, which have been shown to be more atherogenic, to large, buoyant LDL particles, which may be less atherogenic. Both drugs increase HDL, though pioglitazone may raise it more than rosiglitazone. The ADA algorithm recommends TZDs as a potential second-line treatment choice for type 2 DM, particularly when medication cost is a major concern or for those with a compelling need to avoid hypoglycemia. They can be used in combination with metformin and other second-line options.[31,32]

The effects of TZDs on macrovascular complications are controversial and are not similar between rosiglitazone and pioglitazone. A meta-analysis published in 2007 reported higher rates of myocardial infarction (MI) with rosiglitazone compared to placebo or other diabetes medications.[63] This prompted a safety communication from the FDA and prescribing restrictions for the drug. These restrictions were later removed after re-evaluation of the data determined no increased risk. The prospective, multicenter, open-label trial found that rosiglitazone was noninferior to the metformin/sulfonylurea comparator for all CV outcomes except heart failure.[64,65] Alternatively, pioglitazone has been associated with benefits related to macrovascular outcomes. In the PROactive study, 3 years of pioglitazone 45 mg resulted in a significant reduction of the composite of all-cause mortality, nonfatal MI, or stroke in patients with type 2 DM who had previous macrovascular events.[66] Pioglitazone has also been shown to decrease the risk of recurrent strokes, but this was not in a diabetes population.

Adverse effects of TZDs include edema, new-onset or worsening of preexisting heart failure, weight gain, and bone fractures. TZDs cause fluid retention due to peripheral vasodilation and improved insulin sensitization at the kidney with a resultant increase in renal sodium and water retention. Resultant effects include peripheral edema, heart failure, hemodilution of hemoglobin and hematocrit, and weight gain. Peripheral edema is reported in 4% to 5% of patients using TZD monotherapy, but the incidence is significantly increased (more than 15%) when a TZD is used in combination with insulin. TZDs are contraindicated in patients with New York Heart Association Class III and IV heart failure, and great caution should be used in patients with Class I and II heart failure. Edema is dose-related and if not severe, a reduction in the dose may allow the continuation of therapy in the majority of patients. Rarely, TZDs have been reported to worsen macular edema of the eye. Weight gain is also dose-related and is a result of both fluid retention and fat accumulation. Average weight gain varies but a 4-kg weight gain is not uncommon; higher amounts of weight gain may necessitate discontinuation of therapy.

TZDs have also been associated with an increased fracture rate in the upper and lower limbs of postmenopausal women. The risk may relate to TZDs' effect on the pluripotent stem cell and shunting of new cells to fat instead of osteocytes as well as altering osteoblasts/osteoclasts.[67,68] A patient's risk factors for fractures should be considered before selecting a TZD.

TZDs have also been linked to bladder cancer. Bladder tumors have been noted in rodent models using TZDs. Interim analysis of a 10-year observational study with pioglitazone reported an excess of three cases of bladder cancer per 10,000 patient-years of treatment after 5 years of pioglitazone use. Ten-year data using the same database showed no association.[69,70] Other population-based and prospective studies have also reported increased risk with pioglitazone. Excess risk, if present, appears to be mostly in men and smokers, and is dose and duration associated. TZDs should not be used in patients with active bladder cancer and the benefits and risks should be carefully considered before using pioglitazone in patients with a history of bladder cancer.

Premenopausal anovulatory patients may resume ovulation on TZDs due to their insulin-sensitizing effects. Adequate pregnancy and contraception precautions should be explained to all women capable of becoming pregnant.

The recommended starting dosage of pioglitazone is 15 mg once daily and rosiglitazone is 2 mg once daily. Dosages may be increased after 3 to 4 months based on the response to treatment and side effects. The maximum dose and maximum effective dose of pioglitazone is 45 mg and 8 mg once daily for rosiglitazone (Table 94-8). To minimize weight gain and edema, the lowest effective dose should be used. If side effects occur with a higher dose, the dose should be reduced. Lower doses are recommended when used in combination with insulin, and edema and weight gain should be monitored carefully.

Sulfonylureas

Sulfonylureas are oral agents, available in either immediate-release or extended-release formulations, typically dosed once or twice daily (Table 94-8). They enhance insulin secretion by binding to a specific sulfonylurea receptor (SUR1) on pancreatic β-cells. Binding closes an adenosine triphosphate-dependent K^+ channel, leading to decreased potassium efflux and subsequent depolarization of the membrane. Voltage-dependent Ca^{+2} channels open and allow an inward flux of Ca^{+2}. Increases in intracellular Ca^{+2} bind to calmodulin on insulin secretory granules, causing translocation of secretory granules of insulin to the cell surface and resultant exocytosis of the granule of insulin. Elevated secretion of insulin from the pancreas travels via the portal vein and subsequently suppresses hepatic glucose production.

Sulfonylureas are classified as first-generation and second-generation agents. The classification schemes are based on relative potency. First-generation agents (chlorpropamide, tolazamide, and tolbutamide) are lower in potency relative to the second-generation drugs (glyburide, glipizide, and glimepiride), and are rarely used due to a higher risk of adverse effects. When given in equipotent doses, all sulfonylureas are equally effective at lowering BG. On average, glucose-lowering efficacy is considered high with A1C reductions of 1.5% to 2% (0.015 and 0.02; 16 and 22 mmol/mol) and FPG reductions of 60 to 70 mg/dL (3.3-3.9 mmol/L) in drug-naïve patients but is dependent on baseline values and duration of diabetes.

Sulfonylureas are the second most prescribed oral drugs for the treatment of type 2 DM. However, their place in therapy is controversial. Based on their extensive track record of safety and effectiveness, their low cost, and their oral route of administration, many clinicians feel comfortable using them. However, many diabetes experts as well as major organizations that publish guidelines for diabetes management either discourage the use of sulfonylureas or suggest using caution due to the risk of hypoglycemia and weight gain. Soon after sulfonylureas are taken, a robust reduction in A1C is seen, but long-term durability is poor in most patients. Sulfonylureas cause a tachyphylaxis to their insulin secretion effect on the β-cell. In vitro testing of β-cells has reported depolarization of the cell, resulting in its inability to secrete insulin. Whether this effect is reversible is unclear. Clinically, this is recognized by the deterioration of A1C.

Sulfonylureas were used extensively in the UKPDS and ADVANCE trials, which both showed a reduction in microvascular complications in patients targeting a more intensive glycemic goal.[20,24] Results from the University Group Diabetes Program raised early concerns about the CV safety of sulfonylureas, with documented higher rates of coronary artery disease in type 2 DM patients given tolbutamide compared to patients given insulin or placebo. Since then, most evidence suggests that sulfonylurea use does not increase macrovascular outcomes or all-cause mortality compared to other active treatments.[20,24,71,72]

The most common side effect of sulfonylureas is hypoglycemia. Due to its active metabolite, glyburide has a higher risk of hypoglycemia compared to other sulfonylureas while glipizide and glimepiride have lower risks.[72,73] Those who skip meals, exercise vigorously, or lose substantial amounts of weight are more prone to experiencing hypoglycemia. A lower dose should initially be used in high-risk patients, in addition, hypoglycemia on low-dose sulfonylureas may dictate a switch to therapy with a low risk of hypoglycemia. Severe hypoglycemia on sulfonylureas would warrant the same intervention. Because of their risk of hypoglycemia, sulfonylureas should be avoided or used with extreme caution in older adults.[28]

Weight gain is common with sulfonylureas—typically 1 to 2 kg. Whenever possible, clinicians should avoid the use of medications that cause weight gain in patients who are overweight or obese.[74] Many patients report having a sulfa allergy, but cross-reactivity with sulfonylureas is very rare. However, if the patient has a history of anaphylaxis-type reactions to sulfa, it may be best to use a different class of medication.

The starting dose, usual dose, and maximum dose of sulfonylureas are summarized in Table 94-8. Sulfonylureas with long durations of action or those with active metabolites should be avoided in older patients and those with kidney insufficiency due to the high risk of hypoglycemia; an alternative agent should be selected. Within the sulfonylurea class, glipizide may be the safest alternative. The dosage can be titrated as soon as every 2 weeks based on FPG values to achieve glycemic goals. Immediate-release glipizide's maximal dose is 40 mg/day, but its maximally effective dose is about 15 to 20 mg/day. Indeed, the maximally effective dose of sulfonylureas is typically 60% to 75% of the stated maximum dose.[31,75]

α-Glucosidase Inhibitors

Currently, there are two *α*-glucosidase inhibitors approved by the FDA, acarbose, and miglitol, both of which are taken by mouth before meals. *α*-glucosidase inhibitors competitively inhibit maltase, isomaltase, sucrase, and glucoamylase in the small intestine, delaying the breakdown of sucrose and complex carbohydrates. There is no malabsorption of these nutrients but merely a delay in their absorption. The net effect of this action is to reduce the PPG rise. Distal intestinal degradation of undigested carbohydrates by the gut flora results in gas, CO_2, and methane, as well as the production of short-chain fatty acids, which may stimulate GLP-1 release from intestinal L-cells.

The A1C-lowering effects of the *α*-glucosidase inhibitors are modest. PPG concentrations are reduced by 40 to 50 mg/dL (2.2-2.8 mmol/L) while FPG levels are relatively unchanged. Patients near target A1C with near-normal FPG levels but high PPG levels are candidates for therapy. Due to their mechanism, GI side effects, including flatulence, abdominal pain, and diarrhea, are very common and limit their use. Because of the modest A1C effect and the high rates of unpleasant side effects, the ADA does not include the class on their treatment algorithm, but the AACE/ACE algorithm considers them an alternative option that can be used when other medications may be contraindicated or the patient has intolerances. To effectively lower PPG, *α*-glucosidase inhibitors must be taken three times a day with the first bite of each meal.

Meglitinides

Meglitinides are similar to sulfonylureas, except they have a faster onset and shorter duration of action. By binding to a site adjacent to the sulfonylurea receptor, nateglinide and repaglinide stimulate insulin secretion from the β-cells of the pancreas. As monotherapy, both nateglinide and repaglinide significantly reduce PPG excursions and reduce A1C by approximately 0.8% to 1% (0.008-0.01; 9-11 mmol/mol). Similar to sulfonylureas, the main side effects are hypoglycemia and weight gain. Due to the lack of clinical evidence, their role in therapy is unclear. They are not recommended in the ADA algorithm and are considered a less favorable choice on the AACE/ACE treatment algorithm. Nateglinide or repaglinide should be taken by mouth with each meal, initiated at a low dose, and titrated over time until glycemic control is achieved. These agents may be used in patients with kidney insufficiency and may be a good option for those with erratic meal schedules. Multiple daily dosing may decrease adherence.

Bile Acid Sequestrants

The only bile acid sequestrant approved for the treatment of type 2 DM is colesevelam, an oral once-daily medication. Colesevelam acts in the intestinal lumen to bind bile acid, decreasing the bile acid pool for reabsorption. The mechanism for glucose-lowering is unclear as is its role in the treatment of type 2 DM. A1C-lowering efficacy is modest. Colesevelam reduces LDL-C cholesterol in patients with type 2 DM by 12% to 16%. Colesevelam is weight neutral and has a low risk of hypoglycemia. Although colesevelam lowers plasma glucose and LDL-C, it has not been proven to prevent CV morbidity or mortality. Patients with type 2 DM who need a small reduction in A1C as well as additional LDL-C lowering may be candidates for this agent.

Dopamine Agonists

While bromocriptine has been used to treat Parkinson's disease and other disorders for decades, a new formulation, bromocriptine mesylate, was FDA approved for the treatment of type 2 DM. Bromocriptine used for type 2 DM is a quick-release formulation of the dopamine agonist. The exact mechanism by which it improves glycemic control is unknown. Low hypothalamic dopamine levels, especially upon waking are augmented, which may decrease sympathetic tone and output. These effects are speculated to improve hepatic insulin sensitivity and decrease hepatic glucose output. The A1C-lowering efficacy is modest and its role in the treatment of type 2 DM is unclear.

Amylin Analogs

Pramlintide is a synthetic analog of amylin, differing from amylin by three amino acids. It is given subcutaneously before meals and is used in patients currently treated with insulin. Pramlintide mimics the action of amylin, a neurohormone co-secreted from the β-cells with insulin, and regulates glucose by three key mechanisms: reduces glucagon secretion, slows gastric emptying, and increases satiety.

Pramlintide was the first noninsulin agent approved for patients with type 1 DM. Pramlintide is effective at lowering PPG levels and A1C and can be an attractive option for some patients as it can also decrease weight and may allow for lower mealtime insulin doses. Pramlintide lowers A1C by approximately 0.6% (0.006; 7 mmol/mol) and produces an average weight loss of 1.5 kg in patients with type 2 DM. In patients with type 1 DM, the average reduction in A1C was 0.4% to 0.5% (0.004-0.005; 5-6 mmol/mol). Pramlintide is primarily used in patients with type 1 DM as adjunctive therapy in patients who are not achieving PPG goals despite maximizing mealtime insulin doses.

The most common adverse effects associated with pramlintide are GI. Nausea occurs in approximately 20% of patients with type 2 DM and 40% to 50% of patients with type 1 DM. Vomiting or anorexia occurs in approximately 10% of patients. GI adverse effects decrease over time and are dose-related, thus starting with a low dose and slowly titrating as tolerated is recommended. Pramlintide alone does not cause hypoglycemia, but when used in patients on insulin hypoglycemia can occur. To minimize the risk of severe hypoglycemia, the dose of mealtime insulin should be empirically reduced by 30% to 50% when pramlintide is initiated.

Pramlintide dosing is different in patients with type 1 DM and type 2 DM. In type 2 DM, the starting dose is 60 mcg prior to meals and is titrated to the maximally recommended 120-mcg dose as tolerated and warranted based on PPG concentrations. In type 1 DM, dosing starts at 15 mcg prior to meals and can be titrated up in 15-mcg increments to a maximum of 60 mcg prior to each meal, if tolerated.

TREATMENT - Type 2 Diabetes

Hyperglycemia management in patients with type 2 DM should be patient-centered, using shared decision-making and a stepwise approach. The treatment approach should place emphasis on compelling evidence, avoidance of unwanted adverse effects, and minimizing hypoglycemia and weight gain. Management decisions should focus on the impact on comorbidities in addition to the impact on glycemia. Upon diagnosis of type 2 DM, the clinician should assess key patient characteristics including current lifestyle, existing comorbidities, clinical characteristics including A1C, age, weight, presence or absence of symptoms, as well as motivation, cultural preferences, health literacy level, and cost limitations. A patient-specific A1C target should be set and discussed with the patient.

Initial Therapy

Comprehensive lifestyle modifications (medical nutrition therapy [MNT], physical activity, weight loss, smoking cessation, and psychological support) should be implemented at the time of diagnosis and reinforced at every visit since they are the foundational components of diabetes management. To achieve lifestyle modification goals, all patients with type 2 DM should be offered access to ongoing DSME/S programs.

MNT should include improved diet quality and calorie restriction for weight loss or weight maintenance. There is no specific recommended ratio of macronutrients for type 2 DM. Instead, patients should focus on eating patterns that promote foods of demonstrated health benefits and minimize foods of demonstrated harm. All overweight or obese patients should be encouraged to participate in intensive lifestyle management programs to lose weight, with an initial weight loss goal of 5%. Increased physical activity should be encouraged in all patients with type 2 DM to improve glycemic control. Most adults should engage in at least 150 minutes of moderate or vigorous intensity aerobic physical activity spread over the week with no more than 2 consecutive days without activity.[29]

Patients with type 2 DM should consider the quantity, quality, and timing of carbohydrate intake in their diet as a strategy to minimize glucose excursions. Patients should increase carbohydrate intake from vegetables, fruits, legumes, whole grains, and dairy products and should decrease processed foods, refined carbohydrates (ie, foods made with white flour or sugar), or foods/drinks high in added sugar (eg, soda, candy).[29] Quantities of carbohydrates should be considered, although the scientific evidence for specific recommendations is lacking. Education materials often encourage patients to limit daily carbohydrate intake to no more than 60 to 75 g/meal for men or 45 to 60 g/meal for women, and 15 g for snacks. An easier strategy is to limit the grain/starch of the meal to one-quarter of a 9-in. (23 cm) plate. Carbohydrate intake should be spread out across all meals and snacks.

⑨ In addition to comprehensive lifestyle modification, metformin should be started as first-line therapy in patients who do not have contraindications or tolerability issues. This is based on the efficacy, safety, tolerability, cost, clinical evidence, and extensive experience with this medication. Metformin should be started at a low dose and titrated to the maximum effective dose over time to improve tolerability.[31,32]

If a patient's initial A1C is close to goal (eg, ≤7.5% [0.075; 58 mmol/mol]) and the patient is motivated to initiate lifestyle modifications, the clinician could consider initial treatment with lifestyle alone.[31] Since the effectiveness of most oral medications rarely exceeds a 1% (0.01; 11 mmol/mol) reduction in A1C, the clinician may consider starting two medications (metformin plus a second agent) if a patient's initial A1C is more than 1.5% (0.015; 16 mmol/mol) higher than the target A1C.[32] In addition, there is data to support that initial combination therapy can reduce glucose faster and maintain glycemic control for longer compared to a stepwise approach.[32] Early introduction of basal insulin should be considered in patients with very high A1C levels (>10% [0.10; 86 mmol/mol]), those with symptoms of hyperglycemia, or those with evidence of catabolism (eg, weight loss).[32]

To avoid therapeutic inertia, treatment should be reassessed and modified regularly. Patients not meeting their goals should be seen at least every 3 months. Those that are meeting their goals should be seen at least every 6 months. At these points of reassessment, an A1C level should be drawn, medication adherence should be evaluated, and lifestyle recommendations should be reinforced. If glucose targets have not been met, additional therapy should be added.[31,32]

Stepwise Addition of Medications

⑩ Type 2 DM is a progressive disease, and the majority of patients will eventually require combination therapy. Intensification beyond metformin monotherapy requires careful consideration of patient- and drug-related factors when determining the best regimen for a given patient. Patient-specific factors to consider when selecting a medication include the individualized A1C target and the presence of specific comorbidities (eg, ASCVD, heart failure, CKD, obesity). Drug-specific factors to consider include glucose-lowering efficacy, impact on other comorbidities, impact on weight and hypoglycemia risk, side effect profile, ease of use, and cost (Table 94-11).[31,32]

TABLE 94-11

Considerations When Selecting Pharmacotherapy for Type 2 Diabetes

Medication class	Primary Physiologic Action	A1C Reduction Efficacy	Hypoglycemia Risk[a]	Effect on Weight	ASCVD Effects	Cost	Oral/SC	Adverse Effects and Safety
Metformin	↓ hepatic glucose production	High	No	Neutral	Potential benefit	Low	Oral	GI (diarrhea), B12 deficiency
SUs	↑ insulin secretion	High	Yes	Gain	Neutral	Low	Oral	Hypoglycemia, weight gain
TZDs	↑ insulin sensitivity	High	No	Gain	Potential benefit (pioglitazone)	Low	Oral	Edema, weight gain, risk of heart failure, bone fractures, bladder cancer
DPP-4 inhibitors	↑ insulin secretion (glucose dependent); ↓ glucagon secretion (glucose dependent)	Intermediate	No	Neutral	Neutral	High	Oral	Risk of heart failure, pancreatitis, joint pain
SGLT-2 inhibitors	Blocks glucose reabsorption by the kidney, increasing glucosuria	Intermediate	No	Loss	Benefit[b] (empagliflozin, canagliflozin)	High	Oral	GU infections, risk of volume depletion, hypotension, risk of amputations, bone fractures (canagliflozin), risk of DKA
GLP-1 RAs	↑ insulin secretion (glucose dependent); ↓ glucagon secretion (glucose dependent); slows gastric emptying; ↑ satiety	High	No	Loss	Benefit (liraglutide, semaglutide, dulaglutide)	High	SC/Oral	GI (nausea, vomiting), injection site reactions, risk of thyroid C-cell tumors, pancreatitis, cholelithiasis
Basal Insulin	↑ glucose disposal; ↓ hepatic glucose production; suppresses ketogenesis	High	Yes	Gain	Neutral	High	SC	Hypoglycemia, weight gain, injection site reactions

ASCVD, atherosclerotic CV disease; DKA, diabetic ketoacidosis; DKD, diabetic kidney disease; DPP, dipeptidyl peptidase; GI, gastrointestinal; GLP, glucagon-like peptide; GU, genitourinary; RA, receptor agonist; SC, subcutaneous; SGLT, sodium-glucose co-transporter; SU, sulfonylurea; TZD, thiazolidinedione.

[a] When used as monotherapy.

[b] Specific drugs listed as beneficial are based on current available evidence. It is not clear whether the benefit is a class effect.

The first consideration is whether the patient has indicators of high risk or established ASCVD, CKD, or HF. Because of evidence from CV outcome trials, SGLT-2 inhibitors or GLP-1 RAs with proven CV benefit (canagliflozin, empagliflozin, dulaglutide, liraglutide, or SC semaglutide) are recommended as compelling agents to reduce the risk of major adverse CV events in patients with high risk or established ASCVD. If HF coexists, SGLT-2 inhibitors with a proven benefit of reducing HF progression (empagliflozin, canagliflozin, dapagliflozin) are recommended. In patients with CKD, SGLT-2 inhibitors with primary evidence of reducing CKD progression (canagliflozin, dapagliflozin) are preferably recommended. If an SGLT-2 inhibitor is contraindicated or not tolerated, a GLP-1 RA with proven CVD benefit is recommended.[31] TZDs should be avoided in patients with HF. If the A1C target is not achieved after 3 months of dual therapy or if the patient did not tolerate the selected drug, then triple therapy is warranted and a drug from the other class can then be added.[31] These recommendations are independent of baseline A1C, individualized A1C target, or metformin use. In other words, one of these medications should be added irrespective of the need for glucose control and this recommendation is actionable whenever these comorbidities become new clinical considerations regardless of background glucose-lowering medications.

In those without established ASCVD, CKD, or HF, other considerations should be taken into account. If there is a compelling need to minimize weight gain or promote weight loss, GLP-1 RAs or SGLT-2 inhibitors are preferred. GLP-1 RAs have demonstrated varying amounts of weight loss in clinical studies, with the greatest weight loss seen with semaglutide followed by liraglutide, dulaglutide, exenatide, and lixisenatide. If dual therapy does not achieve glycemic control, a drug from the other class can be added. If a GLP-1 RA or an SGLT-2 inhibitor cannot be used, a weight-neutral medication such as a DPP-4 inhibitor can be selected. Sulfonylureas, insulin, and TZDs are not preferred and should be used cautiously due to weight gain. If there is a compelling need to minimize hypoglycemia, DPP-4 inhibitors, GLP-1 RAs, SGLT-2 inhibitors, or TZDs could be added to metformin. If dual therapy does not achieve glycemic control, a drug from a different recommended class can be added. DPP-4 inhibitors and GLP-1 RAs should not be used together due to similar physiologic actions. Basal insulin and sulfonylureas are not preferred in this setting as they increase the risk of hypoglycemia and should be considered only if necessary and used with caution. If there is a compelling need to minimize cost, sulfonylureas or TZDs can be considered.[32]

Addition of Injectable Medications

The approach to insulin use in type 2 DM is quite different than in type 1 DM. People with type 1 DM initiate intensive insulin regimens shortly after diagnosis and require basal and prandial insulin to achieve glycemic control. People with type 2 DM can often be managed with oral medications for years before the addition of insulin is needed. Insulin is recommended for patients with extreme (A1C>10% [0.10; 86 mmol/mol]) or symptomatic hyperglycemia. Otherwise, GLP-1 RAs are preferred over insulin as the first injectable agent. GLP-1 RAs have demonstrated equal or superior A1C-lowering efficacy compared to basal insulin and lead to weight loss instead of weight gain with a low risk of hypoglycemia. Most GLP-1 RAs are started at a low dose and titrated slowly to improve tolerability. If additional glucose-lowering is needed after the GLP-1 RA dose has been maximized, basal insulin can be initiated. Switching to a fixed-ratio combination of GLP-1 RA plus basal insulin could be considered as well. Basal insulin is started at a low dose (10 units once daily or 0.1-0.2 units/kg/day) and titrated slowly over time to a target FPG range. Many titration strategies are used in clinical practice. A common method is the 3-0-3 method where the patient checks FPG levels daily for 3 days and calculates the average of those three readings. If the average is greater than 130 mg/dL (7.2 mmol/L), then the patient increases the dose by 3 units. The patient continues this titration until achieving target FPG levels (ie, 80-130 mg/dL [4.4-7.2 mmol/L] for patients targeting an A1C<7% [0.07; 53 mmol/mol]) or until they have reached a basal insulin dose of 0.7-1.0 units/kg/day. If unexplained hypoglycemia occurs, the dose is decreased by 3 units. If the A1C target is not reached by maximally titrating basal insulin, it indicates that PPG levels are likely elevated. Thus, at that point, a medication that lowers PPG can be considered. GLP-1 RAs or SGLT-2 inhibitors should be considered if the patient is not already taking one. Prandial insulin is also an option. A stepwise approach is recommended when initiating prandial insulin; starting with 4 units or 10% of the basal dose with the largest meal of the day. If the A1C is < 8% (0.08; 64 mmol/mol), the basal dose can be decreased by the same amount to avoid hypoglycemia. The dose should be titrated over time to achieve target PPG levels <180 mg/dL (10.0 mmol/L). A second or third injection can be added to the other meals if needed. The addition of prandial insulin requires more SMBG and patient knowledge and awareness of the relationship between insulin and carbohydrates. It also increases the risk of hypoglycemia and weight gain.[31,32]

It is important to re-evaluate the appropriateness of oral medications when a patient starts injectable agents. GLP-1 RAs can be used in combination with all oral agents except DPP-4 inhibitors. When insulin is started, metformin should be continued. TZDs should be stopped or the dose should be reduced. Sulfonylureas should be stopped or the dose should be reduced, especially if prandial insulin is initiated. SGLT-2 inhibitors can be continued, although the patient should be educated about the risk of DKA, and DPP-4 inhibitors can be continued.[32]

Guideline Recommendations

Several organizations such as the ADA and AACE offer guidance for hyperglycemia management in patients with type 2 daibetes. The ADA and AACE guidelines are similar, in that they both recommend a stepwise approach to treatment, with lifestyle modifications and metformin as first-line therapy, followed by the addition of medications from other classes. They also recommend the use of SGLT-2 inhibitors or GLP-1 RAs in patients with established or high ASCVD risk and/or CKD, independent of glycemic control. The AACE guidelines recommend a more aggressive A1C target (<6.5% [0.065; 48 mmol/mol]) for most patients. Dual therapy is recommended initially for any patient with an A1C>7.5% (0.075; 58 mmol/mol) and insulin is recommended for patients with an A1C>9% (0.09; 75 mmol/mol) with symptoms. Finally, the AACE treatment algorithm lists drugs in order of preference with a focus on minimizing hypoglycemia, weight gain, and other adverse effects.[26]

TREATMENT - Type 1 Diabetes

⑪ Due to the absolute deficiency of endogenous insulin in people with type 1 DM, exogenous insulin therapy is a requirement. Achieving adequate glycemic control in type 1 DM usually requires intensive insulin therapy. Intensive insulin regimens are designed to provide insulin in a manner that mimics normal physiologic insulin secretion (Fig. 94-7), with the consistent secretion of basal insulin throughout the day to manage glucose levels overnight and in between meals (ie, basal insulin), and bursts of insulin in response to glucose rises after the ingestion of carbohydrates (ie, prandial insulin).

FIGURE 94-7

Relationship between insulin and glucose over the course of a day. Blood glucose values in mg/dL can be expressed in mmol/L by multiplying by 0.0555.

The ADA Standards of Care indicate that most people with type 1 DM should be treated with intensive insulin regimens, either multiple daily injections (MDI) or use of continuous subcutaneous insulin infusion (CSII) via an insulin pump.[31] The choice of which delivery method to use should be tailored to the individualized needs and preferences of the person with type 1 DM. Intensive insulin therapy is complex because it requires multiple injections or pump boluses per day in addition to basal insulin, routine monitoring, and collaborative decision-making. The most successful therapy is delivered and adjusted based on changes in nutritional intake, glucose levels, stress, and physical activity.

Examples of intensive insulin regimens are portrayed in Fig. 94-8. A common MDI approach is one injection of long-acting insulin (eg, insulin glargine U-100) to provide the basal component and three injections of rapid-acting insulin (eg, insulin lispro U-100) to provide the prandial component. This regimen utilizes insulin products with more ideal PK properties, but the cost can be prohibitive. A less expensive option consists of two injections of intermediate-acting insulin (eg, NPH insulin) and two injections of short-acting insulin (eg, regular insulin). However, the ADA Standards of Care recommend that most individuals with type 1 DM should use rapid-acting insulins as opposed to regular insulin to reduce the risk of hypoglycemia.[31]

FIGURE 94-8

Common insulin regimens. (A) Multiple-component insulin regimen consisting of one injection of long-acting insulin (^detemir, glargine, degludec) to provide basal glycemic coverage and three injections of rapid-acting insulin (*aspart, lispro, glulisine) to provide glycemic coverage for each meal. (B) Insulin regimen consisting of two injections of intermediate-acting insulin (NPH) and rapid-acting insulin (*aspart, lispro, glulisine [solid red line]), or short-acting regular insulin (green dashed line). Only one formulation of short-acting insulin is used. (C) Insulin administration by an insulin infusion device. The basal insulin rate is decreased during the evening and increased slightly prior to the patient awakening in the morning. Rapid-acting insulin (aspart, lispro, or glulisine) is used in the insulin pump. *(Reproduced, with permission, from Lebovitz HE, ed. Therapy for Diabetes Mellitus and Related Disorders. 4th ed. Alexandria, VA: American Diabetes Association; 2004.)*

Insulin pump therapy or CSII infuses rapid-acting insulin to cover both the basal and prandial insulin needs. The pump infuses a basal rate constantly throughout the day and allows the patient to give bolus doses using a bolus dose calculator based on current glucose levels, carbohydrate intake, and insulin on board. Insulin pump therapy can provide more precise glucose control and allow more flexibility and fine-tune tailoring. However, CSII requires significant patient education and support and both MDI and CSII can achieve good glycemic control. Insulin pump technology is advancing quickly with new-generation devices entering the market regularly.

When initiating insulin therapy in someone with newly diagnosed type 1 DM, the starting dose is typically 0.4 to 1.0 units/kg/day of total insulin. The total daily dose of insulin is then divided to give 50% as basal insulin and 50% as prandial insulin (distributed across meals). As an example, an 80-kg patient initiated on 0.5 units/kg/day would start with a total daily dose of 40 units. He could be initially prescribed 20 units of a long-acting insulin such as insulin detemir or glargine and 7 units of rapid-acting insulin, such as insulin aspart, lispro, or glulisine, with breakfast, lunch, and dinner. The insulin doses would then be adjusted based on SMBG data.

The above example provides a starting point, but there is no one gold standard for starting insulin in patients with type 1 DM. Ideally, patients with type 1 DM should learn how to count carbohydrates so they can match their prandial insulin doses to their carbohydrate intake. Patients should also SMBG before each meal or use CGM to evaluate the insulin regimen and make treatment decisions. Bolus insulin doses can be better individualized by using carbohydrate to insulin ratios (C:I ratios) and correction factors (CF). The C:I ratio is used to estimate how many grams of carbohydrate each unit of rapid-acting insulin will cover. A typical C:I ratio for a patient with type 1 DM is 15:1, meaning that 1 unit of rapid-acting insulin will cover 15 g of ingested carbohydrates. An initial C:I ratio can be estimated by dividing 550 by the total daily dose of insulin the patient is taking. For example, if a patient was taking 40 units of insulin total per day, then his initial C:I ratio would be 550/40 = 14:1.

The CF is used to reduce high glucose levels detected before meals; it is the expected amount that one unit of insulin will decrease the BG under normal circumstances. The initial CF is estimated by dividing 1650 by the total daily dose. For example, if a patient was taking 40 units of insulin per day, then his CF would be 1650/40 = 41 (which would likely be rounded to 40 for easier use). Once the patient has a C:I and CF established, he can use these before each meal to calculate a specific premeal dose of rapid-acting insulin. For the example above, if the patient expected to eat 60 g of carbohydrates, had a premeal glucose reading of 200 mg/dL (11.1 mmol/L), and a target glucose of 100 mg/dL (5.6 mmol/L), he would take 7 units of rapid-acting insulin (60/14 = 4.3 units for the carbohydrates and 100/40 = 2.5 units for the correction).

The 550 rule and 1650 rule to calculate the C:I and CF are not well studied, and in clinical practice, some clinicians use 500 instead of 550 and others use 1500 or 1800 instead of 1650. Regardless, these calculations provide an initial C:I and CF values that must be re-evaluated and adjusted over time based on glucose monitoring data.

Lifestyle modifications differ between type 1 DM and type 2 DM. Patients with type 2 DM are often encouraged to “count carbs” as a way to prevent glucose excursions after meals. This involves limiting carbohydrates to 45 to 75 g/meal or limiting starches/grains to one-quarter of a 9-in. (23 cm) plate. Patients with type 1 DM count carbs in order to match their prandial insulin dose with their carbohydrate intake using a C:I ratio. To be successful, this requires much more accurate estimations of carbohydrate content than what is needed for type 2 DM management.

Adjunctive Therapy

Pramlintide is an amylin agonist indicated as adjunctive treatment in patients with type 1 DM who are not achieving glycemic targets despite optimization of mealtime insulin. Pramlintide is discussed in more detail earlier in this chapter. In this setting, pramlintide may improve glycemic control and minimize weight gain caused by insulin. However, its use is limited by adverse effects such as nausea and vomiting, modest glucose improvements, increased injections and cost, and increased risk of hypoglycemia. Several other medications have been used off-label and/or are currently being studied as adjunctive therapy in type 1 DM, including the SGLT-2 inhibitors and GLP-1 RAs.

HYPOGLYCEMIA

Hypoglycemia is a common complication of some diabetes medications, including insulin, sulfonylureas, and meglitinides, and a major limiting factor to optimal glycemic control. Hypoglycemia can range in severity and is classified as level 1 (hypoglycemia alert value; ≤70 mg/dL [3.9 mmol/L]) which may not cause symptoms but is sufficiently low that it should be treated with a fast-acting carbohydrate; level 2 (clinically significant hypoglycemia; <54 mg/dL [3.0 mmol/L]) which is sufficiently low to indicate serious, clinically important hypoglycemia; and level 3 (severe hypoglycemia) which is associated with cognitive impairment requiring external assistance for recovery and can be life-threatening.[16] Hypoglycemia is associated with falls, injury, motor vehicle accidents, decreased quality of life, as well as an increased risk of CV events, QT prolongation, arrhythmias, and death. Recurrent hypoglycemia increases the risk of developing dementia, and the degree of cognitive impairment has been associated with the frequency and severity of hypoglycemia. All patients taking medications that can cause hypoglycemia should be educated about the prevention, detection, and treatment of hypoglycemia. SMBG is essential to detecting hypoglycemia and taking appropriate action.

Patients can present with a variety of symptoms during an episode of hypoglycemia. Initial autonomic symptoms can include tachycardia, palpitations, sweating, tremors, and hunger. β-blockers may mask some of these early symptoms. Neuroglycopenic symptoms often occur when the BG is <60 mg/dL (3.3 mmol/L) and can include cognitive impairment, confusion, behavioral changes, anger, irritability, blurred vision, headaches, seizures, and loss of consciousness. It is important for patients to self-monitor their BG when symptoms occur to confirm that the glucose is <70 mg/dL (3.9 mmol/L).

Some patients may experience hypoglycemia unawareness, defined as the asymptomatic onset of hypoglycemia. These patients are unable to detect the early warning symptoms of hypoglycemia and are thus at increased risk for the serious sequelae associated with severe hypoglycemia. Patients with hypoglycemia unawareness are typically those with longstanding disease, more stringent glycemic control, and frequent episodes of hypoglycemia. These patients should check their BG levels prior to any activities that require them to be alert and oriented (eg, driving). CGM can be particularly helpful to identify hypoglycemic events in patients with hypoglycemia unawareness. Also, temporarily raising glucose targets may reverse hypoglycemia unawareness.

Prevention of hypoglycemic events is a critical component of diabetes management. SMBG can be helpful but may not be frequent enough to identify hypoglycemia. CGM can be particularly useful in preventing hypoglycemia since it provides the patient with glucose trends which patients can use to adjust their management decisions prior to becoming hypoglycemic. Patients must be educated to understand situations that increase their risk of hypoglycemia, including delaying meals, during or after exercising, or fasting for blood tests or procedures.

Treatment of hypoglycemia dictates the ingestion of carbohydrates. Glucose is preferred. Patients should be counseled to carry a source of fast-acting glucose with them at all times. The "rule of 15" is commonly used to teach patients the proper treatment. First, the patient should perform SMBG to confirm a glucose <70 mg/dL (3.9 mmol/L) and then ingest 15 g of fast-acting carbohydrates (1/2 cup [125 mL] of milk, juice, or soda, one tablespoon of honey, hard candy, jelly beans, or glucose tablets or gel equivalent to 15 g of carbohydrates). Foods that include protein or fat should not be used acutely to treat hypoglycemia due to the delayed absorption of glucose. SMBG should be repeated in 15 minutes; if the glucose remains <70 mg/dL (3.9 mmol/L), the process should be repeated. Once the BG is normalized, the patient should eat a snack or meal that includes complex carbohydrates and protein to prevent further hypoglycemic episodes.

If the patient is unconscious, IV glucose or glucagon (either via the intramuscular or intranasal route) should be given. Glucagon increases glycogenolysis in the liver and may be given in any situation in which IV glucose cannot be rapidly administered. A glucagon product should be prescribed and readily available to all patients on insulin who have a history of severe hypoglycemia or are at high risk for such events. Family and close friends of the patient should be educated regarding the preparation and administration of glucagon. It can take 10 to 15 minutes for the injection to start raising glucose levels and patients often vomit. It is important to position the patient on the side with the head tilted slightly downward to avoid aspiration. New glucagon products have been recently approved that make glucagon administration easier; a pre-filled syringe that is administered intramuscularly but does not require reconstitution and a dry powder nasal spray that is administered intranasally.

Finally, clinicians should inquire about hypoglycemia at every visit. This involves asking the patient about the frequency, severity, and timing of hypoglycemic events, the need for assistance by a third party, or the need to administer glucagon. Patients experiencing frequent or severe hypoglycemia should have their treatment regimen re-evaluated with a goal of minimizing hypoglycemia.

COMPLICATIONS AND COMORBIDITIES

Achieving good glycemic control is important to reduce the risk of both short-term and long-term complications in patients with type 1 or type 2 DM.[14] Short-term complications include symptoms of excessive urination, fatigue, and weight loss. In patients who are ketosis-prone, sustained elevations of BG above 200 to 300 mg/dL (11.1-16.7 mmol/L) can lead to DKA, a potentially life-threatening condition that often requires hospitalization to receive IV fluids and electrolytes. (See Chapter e95, "Acute Hyperglycemia.") Even in patients who are not prone to ketosis, prolonged periods of poor glycemia can lead to HHS. Poor glycemic control can lead to an increased risk of soft-tissue and urinary tract infections, even in the short term. Long-term complications are the result of vascular and tissue damage. Long-term complications include ASCVD leading to CV events, nephropathy often resulting in kidney insufficiency, retinopathy potentially leading to vision loss, and neuropathy that can cause a wide variety of debilitating symptoms. The combination of vascular damage, peripheral nerve dysfunction, and a diminished immune response significantly increase the risk of toe, foot, and leg amputations in patients with diabetes. Males with diabetes are more prone to developing erectile dysfunction. In short, diabetes can negatively impact nearly every organ system throughout the body, and therefore a very comprehensive approach to patient monitoring is required.

Macrovascular Complications

⑫ Macrovascular complications are the leading cause of death in people with diabetes. The risk for coronary heart disease (CHD) and ischemic stroke is two to four times greater in patients with diabetes when compared to individuals without diabetes.[51] Moreover, CV disease is the leading cause of mortality in patients with DM. Addressing CV risk factors—lipids, hypertension, smoking cessation, and antiplatelet therapy—will reduce macrovascular events. The ADA recommends low-dose aspirin therapy (75-162 mg daily) in all patients who have established ASCVD. If the patient is allergic to aspirin, clopidogrel may be used. The role of antiplatelet therapy for the primary prevention of a CV event in patients with diabetes is unclear. While low-dose aspirin reduces the risk of vascular events, in adults who do not have established ASCVD the benefits are offset by a higher risk of major bleeding.[77] Some clinical practice guidelines recommend aspirin therapy if the 10-year risk of a CV event is greater than 20% and the patient is at relatively low risk for bleeding complications. In patients who are older than 70 years of age, the risks outweigh the potential benefits of using antiplatelet therapy for the primary prevention of a CV event.

In patients with diabetes and established ASCVD, the use of a GLP-1 RA or an SGLT-2 inhibitor should be strongly considered.[78] Several agents in these two classes of medications have been shown in clinical trials to reduce the risk of major cardiovascular adverse events in patients with a history of coronary artery disease, myocardial infarction, ischemic stroke, or peripheral artery disease and those at very high risk of vascular events with multiple ASCVD risk factors in addition to diabetes. The SGLT-2 inhibitors, specifically empagliflozin, canagliflozin, and dapagliflozin, significantly reduce the risk of hospitalization due to heart failure. Therefore, this class is preferred in patients with preexisting heart failure or those who are at high risk of developing heart failure due to structural heart disease.

Following a myocardial infarction, β-blocker therapy protects patients with diabetes from recurrent CHD events, and the magnitude of benefit is greater than that seen in patients without diabetes.[79] While the adrenergic symptoms produced by hypoglycemia (eg, tachycardia, tremor) can be masked by β-blockers, sweating and neuroglycopenic symptoms are not. Therefore, β-blockers should not be withheld in patients with diabetes if there is a compelling indication to use them.

⑬ High blood pressure increases the risk of both microvascular and macrovascular complications in patients with DM.[51] The ADA recommends dietary changes, specifically the Dietary Approaches to Stop Hypertension (DASH), and increased physical activity be instituted for all patients whose BP exceeds 120/80 mm Hg. Weight loss is also recommended in those patients who are overweight or obese. Pharmacological therapy, preferably using a class of agents proven to reduce CV event rates, should be instituted if the patient's confirmed office-based BP exceeds 140/90 mm Hg. A combination of two medications should be used if the blood pressure exceeds 160/100 mm Hg. The ADA recommended thresholds and targets for treatment are slightly different than those recommended by the American College of Cardiology/American Heart Association guidelines.[80] While epidemiological data and clinical trials support a blood pressure target of less than 130/80, studies that used intensive BP targets often excluded patients with diabetes.[81] The ACCORD-BP study failed to find a significant benefit when patients with diabetes and ASCVD or multiple CV risk factors were treated to a systolic BP target less than 120 mm Hg when compared to patients treated to a 130 to 140 mm Hg target.[82] The ADA guidelines suggest that a lower target, such as 130/80 mm Hg, is appropriate in patients at high risk of CV events (ie, 10-year ASCVD risk > 15%) but does not give this a grade A recommendation due to the lack of high-quality data in patients with diabetes.

Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are often used as the initial pharmacological treatment for high blood pressure in patients with diabetes due to their well-documented CV and kidney protective effects.[51] However, thiazide diuretics and CCB have also been shown to improve outcomes in patients with diabetes. Most patients require multiple agents, on average three, to attain the BP goals. Thus, diuretics and calcium channel blockers frequently are used in combination with an ACE inhibitor or ARB. For more information regarding the treatment of hypertension in patients with diabetes, see Chapter 30, "Hypertension."

High-intensity statin therapy is recommended in all patients with diabetes and pre-existing ASCVD.[51] In the absence of ASCVD, a moderate-intensity statin should be prescribed to all patients with type 1 or type 2 DM over the age of 40. In patients younger than 40 years of age, moderate-intensity statin therapy may be appropriate if the patient has multiple CV risk factors.[83] The benefits of statins for the primary prevention of CV events in patients with diabetes were established in the Collaborative Atorvastatin Diabetes Study (CARDS).[84] Patients with diabetes and no documented ASCVD were randomized to atorvastatin 10 mg daily or placebo. The trial was stopped early because major CV events were reduced by 37% in the atorvastatin-treated patients. Data from the Heart Protection Study (HPS) also affirm the benefit of statin therapy. Simvastatin 40 mg daily reduced the risk of a major CV event in patients with diabetes by nearly 25% when compared to placebo-treated patients. Statin therapy is recommended regardless of baseline lipid or LDL-C levels. Because statins may cause birth defects, they should only be used in women of childbearing age who do not wish to become pregnant and are using a reliable form of contraception.

After a statin has been initiated for CV risk reduction, markedly elevated triglycerides (≥500 mg/dL [5.65 mmol/L]) may require additional therapy.

Patients with marked hypertriglyceridemia are at risk for pancreatitis. In these circumstances, a fibrate (eg, fenofibrate), omega-3 fatty acid, or niacin can be used to reduce serum triglycerides.[85] The routine use of medications to address hypertriglyceridemia in patients with diabetes with baseline elevations less than 500 mg/dL (5.65 mmol/L) is controversial. The Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) was conducted in patients with type 2 DM and failed to show a CV benefit from fenofibrate 200 mg daily when compared to placebo. In a subgroup analysis, subjects without ASCVD at baseline appeared to have a significant reduction in CV events. However, the lipid arm of the ACCORD study also evaluated the use of fenofibrate, and it did not significantly lower CV events. Niacin in combination with a statin failed to improve CV outcomes in patients with diabetes as well.

Peripheral arterial disease is another potential macrovascular complication associated with diabetes, which often contributes to foot ulcers and limb amputation.[51] Claudication and nonhealing foot ulcers are common in patients with type 2 DM. Smoking cessation, statin therapy, good glycemic control, and antiplatelet therapy are important strategies in treating peripheral arterial disease. Cilostazol may be useful in select patients to reduce symptoms. Revascularization surgery can be considered; however, small vessel disease that cannot be bypassed is common in diabetes. If a patient develops foot lesions, early detection, debridement, and appropriate footwear are critical to prevent foot or limb loss. For more advanced lesions, skin grafts, topical wound healing, and hyperbaric treatments may be necessary. Foot examinations during each face-to-face encounter with the patient and a yearly Semmes-Weinstein 10 gram-force monofilament test to assess for loss of protective sensation can be used to identify high-risk patients who need further evaluation, routine podiatric care, and closer follow-up.

Microvascular Complications

Microvascular complications are closely related to glycemic control, and efforts to improve glycemia significantly reduce the risk of developing these complications and slow their progression.[86] Microvascular complications take many forms but most commonly manifest as damage to the kidneys, eyes, and peripheral nerves.

Nephropathy

DM, particularly type 2 DM coupled with hypertension, is among the leading causes of ESKD in the United States.[86] Albuminuria is a marker of kidney damage and a strong predictor of ESKD in patients with type 1 DM. In type 2 DM, the presence of albuminuria is a strong risk factor for macrovascular disease but a weaker predictor for ESKD. The ADA recommends measuring a patient's eGFR and screening for albuminuria at the time of diagnosis and annually thereafter in persons with type 2 DM. In type 1 DM, proteinuria rarely occurs before puberty. Annually screening individuals with type 1 DM should begin with puberty or when the disease duration has been at least 5 years. Patients with a UACR >300 mg/g or an eGFR 30-60 mL/min/1.73 m^2 should be monitored twice annually to guide therapy. There are three methods for assessing albuminuria: (1) a random spot collection, preferably the first-morning void; (2) a 24-hour timed collection; and (3) a timed (eg, 4- or 10-hour overnight) collection. Modestly elevated albuminuria is defined as a ratio of 30 to 299 mg/g (3.4-33.8 mg/mmol) albumin:creatinine and overt albuminuria as a ratio ≥300 mg/g (33.9 mg/mmol). Timed collections are cumbersome to perform but more accurate than a random spot collection. There is significant day-to-day variability in urinary protein excretion. Therefore, unless the results are unequivocally positive, albuminuria should be confirmed on at least two of three samples over 3 to 6 months. Additionally, when assessing urine protein, conditions that may cause transient elevations in urinary protein or albumin excretion should be excluded. These conditions include intense exercise, recent urinary tract infections, hypertension, short-term hyperglycemia, heart failure, and acute febrile illness.

Glucose and blood pressure control are important for preventing and retarding the progression of nephropathy.[86] The SGLT-2 inhibitors, specifically empagliflozin, canagliflozin, and dapagliflozin, significantly reduce the decline in kidney function in patients with CKD, with or without diabetes. Therefore, this class is preferred in the treatment of type 2 DM in patients with CKD, specifically in those with eGFR 30-60 mL/min/1.73 m^2 and a UACR > 300 mg/g (33.9 mg/mmol). While the glucose-lowering effects of the SGLT-2 inhibitors are substantially reduced when the patient's eGFR is < 45 mL/min/1.73 m^2, the kidney protective effects are not. The GLP-1 RAs also appear to slow the progression of CKD, but these findings have not yet been confirmed in studies specifically designed to determine the impact of GLP-1 RAs on kidney function in patients with CKD.

ACE inhibitors and ARBs have also been shown to slow the progression of kidney disease in patients with diabetes. However, using a combination of agents to block the renin–angiotensin–aldosterone system—for example, using an ACE inhibitor with an ARB, aldosterone receptor blockers, or direct renin inhibitors—has not been shown to improve outcomes but clearly increase the risk of adverse effects. Diuretics frequently are necessary due to the volume-expanded state of patients with CKD and are recommended second-line therapy. The ADA currently recommends a blood pressure goal less than 140/90 mm Hg in patients with nephropathy, but a lower blood pressure target (eg, less than 130/80), if it can be achieved without undue burden or side effects, may be desirable. Three or more antihypertensives are often needed to reach goal blood pressure.

Retinopathy

Diabetic retinopathy is caused by ischemia in the microcirculation in the eye coupled with the inappropriate release of vascular growth factors.[86] Patients with diabetes should have routine dilated eye examinations to fully evaluate the retina. The ADA recommends patients with type 1 DM and patients with established retinopathy be seen by an ophthalmologist or optometrist trained in diabetic eye disease. Early background retinopathy may reverse with improved glycemic control and optimal blood pressure control. More advanced retinopathy will not fully regress with improved glycemia. Aggressive reductions in BG may acutely worsen retinopathy. Laser photocoagulation has markedly improved sight preservation and is recommended in patients with macular edema and proliferative retinopathy. Intravitreal anti-vascular endothelial growth factor (VEGF) therapy has also been shown to be highly effective for sight preservation. Both bevacizumab, used off-label, and ranibizumab are anti-VEGF monoclonal antibodies. Aflibercept is a VEGF decoy receptor. People with diabetes also have a higher rate of cataracts and open-angle glaucoma.

Neuropathy

Neuropathy in people with diabetes can manifest as (1) peripheral neuropathy, (2) autonomic neuropathy, and/or (3) focal neuropathies.[86] Distal, symmetrical, peripheral neuropathy is the most common complication seen in type 2 DM patients in outpatient clinics. Paresthesias, perceived hot or cold, numbness, or pain are the predominant symptoms. The feet are involved far more often than the hands as peripheral nerve damage initially affects longer nerve fibers and progresses proximally. Efforts to improve glycemic control are the primary treatment strategy and may alleviate some of the symptoms. If neuropathy is painful, symptomatic treatments can be used, but they will not change the course of the neuropathy. No medication has been shown to be clearly superior to another for the relief of neuropathic pain, and treatment selection should be based on adverse effects, cost, and convenience. Treatment with low-dose tricyclic antidepressants (preferably nortriptyline or desipramine), duloxetine, gabapentin, pregabalin, venlafaxine, topical capsaicin, and tramadol may be considered. If these are unsuccessful, patients should be referred to a pain clinic or neurologist for further evaluation. Duloxetine and pregabalin are FDA approved for the treatment of neuropathic pain associated with diabetic peripheral neuropathy. For patients with primarily numbness and minimal or no pain, medications are not effective. However, these patients are at high risk for developing foot ulcerations and should be carefully assessed at every face-to-face visit and preferably followed by a podiatrist.

Autonomic neuropathy impacts the autonomic nerves and can lead to resting tachycardia, orthostatic hypotension, chronic constipation, gastroparesis, erectile dysfunction, anhidrosis, heat intolerance, gustatory sweating, dry skin, and hypoglycemic unawareness.[87] Gastroparesis can be a severe and debilitating complication of DM. Improved glycemic control, discontinuation of medications that slow gastric motility, and the use of metoclopramide or low-dose erythromycin may be helpful. Unfortunately, tachyphylaxis to drug therapies develops within days or weeks. Gastric pacemakers can be considered if symptoms are severe and persistent. Domperidone may also be considered. Although it is not approved for use in the United States, domperidone is available in many other countries and can be requested through the FDA for compassionate use. Diabetic diarrhea most frequently occurs at night. Celiac disease, exocrine insufficiency, and gut bacterial overgrowth should be ruled out. Diabetic diarrhea frequently responds to a 10- to 14-day course of an antibiotic such as doxycycline or metronidazole. In more unresponsive cases, octreotide may be used.

If a patient develops orthostatic hypotension, antihypertensive agents should be discontinued, and dietary sodium intake should be liberalized. Some patients may require pharmacologic treatment for orthostatic hypotension with mineralocorticoids (eg, fludocortisone) or adrenergic agonist agents (eg, midodrine). In severe cases, supine hypertension may be extreme, mandating that the patient sleep in a sitting or semi-recumbent position. Patients with cardiac autonomic neuropathy are at a higher risk for silent MI and sudden cardiac death.

Erectile dysfunction is common in diabetes, and initial treatment should include a trial of one of the phosphodiesterase type 5 inhibitors (eg, sildenafil) prior to referral.[86] People with diabetes often require the highest doses of these medications to achieve an adequate response.

Sudomotor dysfunction may cause reduced sweating and dry, cracked skin. The use of hydrating creams and ointments is needed. Autonomic neuropathy may also result in gustatory sweating after eating. If sweating is excessive, it may be treated with antiperspirants or anticholinergic drugs. Hypoglycemic unawareness requires the patient to avoid hypoglycemia, as the body will slowly increase the glycemic level at which it will activate the autonomic signals.

Focal neuropathies occur most often in older patients with poorly controlled diabetes. Cranial nerve III, IV, and VI neuropathies, as well as Bell's palsy, produce quite dramatic symptoms, but the course is usually self-limited—partial or full recovery occurs in a few weeks to months. Diabetic amyotrophy, which is characterized by proximal thigh muscle pain and weakness, can be very debilitating. Carpal tunnel syndrome, caused by radial nerve entrapment in the wrist, is also more common in people with diabetes, and tarsal tunnel syndrome may cause foot paresthesias.

SPECIAL POPULATIONS

Prediabetes and Preventing Type 2 DM

Prediabetes, as the name implies, is a condition that frequently precedes the development of diabetes.[4] Patients with prediabetes do not have marked elevated BG but rather IFG (100-125 mg/dL [5.6-6.9 mmol/L]) or IGT (140-199 mg/dL [7.8-11.0 mmol/L] 2 hours after ingesting a 75 g carbohydrate load) and often an elevated A1C (5.7%-6.4% [0.057-0.064; 39-46 mmol/mol]). None of these abnormal readings is sufficiently high to meet the diagnostic criteria for diabetes. One in three adults in the United States has prediabetes.[2] Most patients with prediabetes are overweight or obese, and many concurrently have high blood pressure and dyslipidemia. This is an important patient population to identify because they are at high risk of eventually developing type 2 DM.

⑭ Given that prediabetes often progresses, there has been significant interest in using both nonpharmacologic and pharmacologic means to prevent or delay the onset of type 2 DM. Weight loss, regular aerobic activity, increased fiber intake, and limiting fat consumption are the four lifestyle pillars for both the treatment and prevention of type 2 DM. The Diabetes Prevention Program (DPP) was a landmark clinical trial that demonstrated that modest weight loss and regular physical activity dramatically reduced the risk of developing type 2 DM in patients with IGT.[88] Patients assigned to the lifestyle intervention group walked 30 minutes per day 5 days per week and lost a mean of 8-lb (3.6 kg) over the 2.8-year study. These lifestyle changes resulted in a 58% reduction in the risk of developing type 2 DM when compared to a usual care group (5% per year vs 11% per year). Diet and exercise interventions were effective regardless of age or baseline weight. A third arm of the study randomized patients to receive metformin 850 mg twice daily. The patients in the metformin arm received usual care and did not engage in intensive lifestyle changes. Metformin use leads to, on average, a 4-lb (1.8 kg) weight loss and reduces the risk of developing type 2 DM by 31% when compared to usual care. Younger and overweight individuals who took metformin experienced the greatest reductions. These findings suggest that metformin use may have the greatest impact when prescribed to middle-aged adults who are obese.

Several other medications have also been shown to delay or prevent diabetes. Rosiglitazone and pioglitazone reduce the risk of developing type 2 DM by 60% to 70% in patients with impaired glucose tolerance.[89,90] Acarbose reduced the risk of developing type 2 DM by 25% in the STOP NIDDM study and may be particularly useful in patients who consume a diet high in starchy carbohydrates such as rice. The GLP1-RAs, liraglutide and semaglutide, have also been shown to slow the progression to type 2 DM, reducing the risk by 80% in obese patients taking the medication for weight loss.[91,92] Insulin glargine reduced the risk of developing type 2 DM by approximately 30% in patients with prediabetes. ACEi or ARBs have also been shown to lower the risk of developing type 2 DM by 25% in a pooled analysis of several large CV studies.[93] Given that many patients with prediabetes concurrently have high blood pressure, an ACEi or ARB should be preferentially used in this population to treat hypertension.

Unfortunately, pharmacological methods to "prevent" diabetes do not cure but rather delay the onset of diabetes. No pharmacologic agent is currently FDA approved for the prevention of type 2 DM. Given its relatively low cost and favorable long-term safety profile, metformin, in conjunction with lifestyle changes, is recommended by the ADA to delay the onset of diabetes in patients with prediabetes, particularly those with a BMI > 35 kg/m^2, those aged <60 years, and women with a history of GDM.[94] Liraglutide and once-weekly semaglutide are attractive options for weight loss in obese patients with prediabetes.

Children and Adolescents with Type 2 DM

The incidence and prevalence of type 2 DM are increasing in adolescence.[95] Obesity and physical inactivity are the likely culprits, but innate genetic susceptibility is also an underlying factor. Given that children will potentially live with diabetes for many decades and that the timeline for microvascular complications mimics that of adults with diabetes, extraordinary efforts should be made to assist the child and the family adopt lifestyle changes that normalize BG. The only FDA-approved oral agent for the treatment of type 2 DM in children (10-16 years of age) is metformin, and, similar to adult guidelines, some experts recommend its routine use in the absence of contraindications. Unfortunately, the durability of the response to metformin monotherapy is relatively poor. Liraglutide and exenatide XR have also recently been approved for use in children (10 years of age and older). Sulfonylureas are also commonly used. TZDs improve glycemic control when added to metformin therapy but are not currently FDA approved for use in children. While the DPP-4 inhibitors are an attractive option because they do not cause hypoglycemia, this class of medications has not been adequately studied in children. Insulin therapy continues to be the standard of care when glycemic goals cannot be achieved or maintained with metformin monotherapy. See Table 94-6 for treatment goals in children and adolescents.

Older Adults

Nearly one in four adults over the age of 65 years has diabetes, and slightly more than half have prediabetes. Older adults, particularly those with functional disability and cognitive impairments, are less able to adopt healthy lifestyle behaviors and more likely to experience adverse effects from medications.[28] The ADA guidelines recommend a patient-centered approach, and there are several factors that should be considered when treating older adults. The number and severity of comorbid conditions, kidney dysfunction, ability to engage in self-care, nutritional status, social support, the risk of falls, and life expectancy should all influence glycemic goals and treatment selection. (See Table 94-6 and Fig. 94-6.) The ADA recommends an A1C goal ≤ 7.0%-7.5% (0.070-0.075; 53-58 mmol/mol) for otherwise healthy older adults who have intact cognitive function, but a less stringent goal A1C ≤ 8.0% (0.080; 64 mmol/mol) is reasonable in those with multiple chronic diseases. In patients who have limited life expectancy, significant cognitive impairments, require long-term care, or are unable to engage in activities of daily living, an A1C should not be used as the primary means to guide therapy. Instead, clinicians should use blood glucose monitoring to keep fasting blood glucose between 100 and 180 mg/dL (5.6 and 10.0 mmol/L) in order to avoid hypoglycemia.

Older adults often have altered perceptions of hypoglycemia and may not experience adrenergic symptoms (eg, tremor, jitteriness, palpitations) due to the age-related loss of autonomic nerve function.[28] Thus, neuroglycopenic symptoms (eg, altered mental status, personality changes) may be the first indication the patient's BG is low. For these reasons, over-treatment of DM should be avoided, and de-escalation should be strongly considered should severe or frequent hypoglycemia occur. Older adults in long-term care facilities are particularly vulnerable to hypoglycemia. However, glycemic control should not be relaxed so far as to cause symptoms of hyperglycemia or risk the development of DKA or HHS.

Other therapeutic goals related to the management of blood pressure and dyslipidemia to prevent the development or progression of kidney disease and CV complications should be similarly tailored in older adults based on the patient-specific circumstances.[28] While a decline in kidney function may preclude the use of metformin in some older adults, lower doses may be used if coupled with more frequent monitoring (eg, every 3 months) of kidney function when the eGFR is consistently above 30 mL/min/1.73 m^2.[28] The efficacy of the SGLT-2 inhibitors decline as kidney function declines, thus older adults typically have a diminished response to this class of agents. SGLT-2 inhibitors may also increase the frequency of urination and cause orthostatic blood pressure changes, increasing the risk of falls.

Sulfonylureas, particularly longer-acting agents such as glyburide and chlorpropamide, are more likely to cause hypoglycemia and should be avoided. A higher risk of distal extremity fracture from falls has been documented with canagliflozin as well as the TZDs. The TZDs often cause fluid retention and increase the risk of congestive heart failure. DPP-4 inhibitors are generally well-tolerated and do not cause hypoglycemia. Similarly, α-glucosidase inhibitors are generally safe and may also be used. The GLP-1 RAs and the SGLT-2 inhibitors are unlikely to cause hypoglycemia and produce a modest weight loss, which can be advantageous in overweight individuals. However, older patients may be more prone to GI side effects from GLP-1 RAs. Simple insulin regimens using a single daily basal insulin dose can be used in older adults, especially if tight glycemic control is not the goal. Both the injectable GLP-1 RAs and insulin therapy require the patient to have adequate motor skills and visual acuity to self-administer doses.

Pregnant Women

The prevalence of DM has increased significantly among women during their reproductive years.[13] In women with type 1 or type 2 DM, discussions about family planning and achieving good glycemic control prior to pregnancy are critical. Organogenesis is largely completed within the first 8 weeks of pregnancy—well before good glycemic control can be achieved in the absence of preconception planning. Unfortunately, major congenital malformations due to poor glucose control in the first trimester of pregnancy remain the leading cause of mortality and serious morbidity in infants of mothers with DM. During preconception planning, all drugs should be reviewed for safety. Known teratogens, such as ACE inhibitors and statins, should be stopped and, if treatment is still needed, an appropriate alternative recommended.

GDM is diagnosed during pregnancy, and all women should be screened for GDM between weeks 24 and 28 of the pregnancy. See Table 94-5. The adverse outcomes associated with GDM include birth defects, miscarriage, cesarean section delivery, maternal preeclampsia/eclampsia, preterm delivery, neonatal hypoglycemia, shoulder dystocia, birth injury, and hyperbilirubinemia.[13] Medical nutritional therapy to minimize wide fluctuations in BG is of paramount importance. Intensive educational efforts are usually necessary. Pregnant women without DM maintain plasma glucose concentrations between 50 and 130 mg/dL (2.8 and 7.2 mmol/L). Normoglycemia is the goal, and failure to maintain this despite dietary interventions will necessitate medication use. Goals during therapy are to keep fasting glucose less than 95 mg/dL (5.3 mmol/L), and either a 1-hour postprandial plasma glucose levels less than 140 mg/dL (7.8 mmol/L) or 2-hour postprandial plasma glucose levels less than 120 mg/dL (6.7 mmol/L). See Table 94-6. Ketosis should also be avoided as much as possible.

Similarly, in patients who have preexisting type 1 or type 2 DM who become pregnant, premeal, bedtime, and overnight SMBG should be less than 95 mg/dL (5.7 mmol/L) with a peak PPG less than 140 mg/dL (7.8 mmol/L). While the A1C during pregnancy should ideally be between 6% and 6.5% (0.06 and 0.065; 42 and 48 mmol/mol), SMBG must be used to guide therapy because it provides daily information about glycemic control. In women with type 2 DM controlled by lifestyle modification alone, conversion to insulin is often necessary soon after the pregnancy is confirmed. Patients previously treated with insulin typically need to intensify the regimen to achieve the more stringent therapeutic goals recommended during pregnancy. This may require the use of more complicated regimens coupled with carbohydrate counting and adjustments guided by SMBG. While NPH remains the recommended basal insulin to use during pregnancy, insulin detemir appears to be safe. Insulin pump therapy can be considered. In highly motivated patients, CSII can achieve excellent glycemic control and is routinely adjusted throughout the pregnancy.

In women with type 2 DM or GDM, both metformin and glyburide have been studied as alternatives to insulin therapy.[13] Both appear to be effective and safe based on the results of small randomized controlled trials and meta-analyses. However, rare or uncommon adverse fetal events are difficult to discern from these data. Glyburide was not detected in the cord serum of any infant in one study, whereas metformin crosses the placenta. Further study in larger patient populations is needed prior to routinely recommending them, but in patients for whom the complexity of insulin is too difficult or refuses insulin, glyburide or metformin use is justified. Patients with GDM should be evaluated approximately 6 weeks after delivery to ensure that normoglycemia has returned. The lifetime risk for the development of type 2 DM is 30% to 50%, making the periodic screening of women with a history of GDM warranted.

Patients with HIV

Patients living with HIV are at higher risk for developing type 2 DM. This risk may be related to HIV infection, concomitant infections such as hepatitis C, and medications often used to treat HIV and its comorbidities. Pentamidine, used for *Pneumocystis carinii* pneumonia infections, is a β-cell toxin and may cause some patients to develop hypoglycemia from insulin release followed by hyperglycemia. Megestrol, used as an appetite stimulant, can have glucocorticoid-like effects and cause hyperglycemia in some patients. Protease inhibitors, used to treat HIV infection, can worsen insulin sensitivity, decrease the ability of the β-cell to secrete insulin, and worsen lipotoxicity. Long-term use of stavudine also increases the risk of developing diabetes. Redistribution of fat from subcutaneous to the visceral compartment from medications or HIV infection also increases the risk of developing diabetes. Metformin is the drug of choice for HIV patients as weight gain can be minimized. Stavudine, zidovudine, and didanosine may cause lactatemia, especially upon long-term use. It may be advisable to check lactate levels in patients taking these medications prior to metformin use. If lactate levels are greater than two times normal, alternative therapy should be considered. If excess visceral adiposity is noted, a TZD that redistributes fat into subcutaneous adipose tissue and causes visceral fat apoptosis may be considered. Drugs that promote weight loss should also be considered. Significant drug-drug interactions may also be present.

EVALUATION OF PATIENT OUTCOMES

Glycemic control can be measured in several ways.[96] Plasma and BG measurements collected during fasting and postprandial periods can be used to determine the patient's current glycemic status. CGM devices collect glucose monitoring data throughout the day. These tests of glycemia are useful for detecting hypoglycemia, making adjustments in insulin therapy, and determining the patient's glycemic patterns. For those using a CGM, time in range (TIR), time below range, and glycemic variability are useful markers of glycemic control. The A1C is the gold standard for determining overall glycemic control for the previous 2 to 3 months and correlates with the risk of developing many of the long-term complications associated with diabetes. Fructosamine, which measures the amount of glycation on plasma proteins such as albumin, is a test of glycemia that can be useful in patients with altered red blood cell lifespan or a hemoglobinopathy. Fructosamine measures glucose control over the previous 2 to 3 weeks. Unfortunately, fructosamine is not as reliable as the A1C, and the correlation between fructosamine measurements and the risk of complications from diabetes is unknown. Thus, glycemic goals based on fructosamine have not been established.

While these glycemic goals recommended by the ADA and AACE are useful general targets, treatment goals need to be individualized. Less stringent A1C goals are appropriate in patients with a history of severe hypoglycemia, limited life expectancy, advanced micro/macrovascular complications or comorbidities, and in patients who are frail, have dementia, or have limited social or financial resources. Less stringent goals should also be set for younger children. Conversely, more aggressive glycemic goals are appropriate in patients who are young or middle-aged adults, newly diagnosed, and using treatments that are unlikely to cause hypoglycemia.

SMBG and CGM are important tools that provide an opportunity to adjust medications, food intake, or physical activity. SMBG and CGM improve safety by enabling patients to detect hypoglycemia so that it can be treated. In general, SMBG frequency should match how frequently medication changes are needed to achieve glycemic control as well as the risk of hypoglycemia. SMBG and CGM empower patients to make day-to-day adjustments in prandial insulin doses and are used to determine if corrective doses of insulin are needed. Even in patients who do not use insulin therapy, SMBG and CGM can be useful to see how a change in diet or exercise impacts BG. SMBG readings are needed to check the accuracy of some CGM devices. For patients with type 1 DM, CGM is generally preferred, but SMBG can be performed four to six times per day—prior to food intake and physical activity as well as at bedtime. The optimal frequency of SMBG and the use of CGM in patients with type 2 DM on oral agents is unknown and its role controversial. SMBG and CGM in patients with type 2 DM may be useful in patients who are actively using the information to make changes in their lifestyle behaviors and for a few weeks after medication changes.

The use of CGM has become increasingly common and helpful in patients using intensive insulin therapy. CGM measures interstitial glucose, which lags behind fingertip capillary SMBG. CGM can be particularly useful in patients with frequent episodes of hypoglycemia, hypoglycemic unawareness, and nocturnal hypoglycemia. CGM can be used to identify glucose patterns and evaluate patients with higher or lower than expected A1C results. Some CGMs must be calibrated using SMBG readings after insertion of a new sensor and periodically thereafter. A new sensor must be placed every 7 to 14 days. CGM data can be transmitted to insulin pumps which can then make recommendations to the patient or automatically adjust the insulin doses based on the results. The ADA currently recommends daily use of personal CGM in patients on intensive insulin therapy to lower or maintain A1C levels and/or reduce hypoglycemia.

Alternate site testing for SMBG performed on the palm, forearm, or thigh is less painful than obtaining blood samples from fingertip samples, but only some BG test strips are designed for alternative site testing. Alternate sites tend to have fewer nerve endings than fingertips and may be more comfortable for a patient. Glucose readings obtained from alternative sites will lag behind fingertip capillary blood by 20 to 30 minutes. Therefore, alternate site testing is discouraged in any situation where immediate action will be needed based on the glucose reading, such as testing for hypoglycemia or when the BG is changing rapidly, such as after a meal.

Choosing an appropriate meter to perform SMBG depends on the patient's dexterity, vision acuity, cost of the meter and strips, and desired features. Insurance coverage often influences meter choice. When a patient first obtains a new glucometer, it is important to demonstrate the testing methods and have the patient perform the technique. Each meter has specifications for hematocrit, elevation, and temperature tolerances for optimal operation.

Medication Adherence and Persistence

Despite the armamentarium of treatment options, a large percentage of patients fail to achieve target A1C and blood glucose levels. One major contributing factor to uncontrolled diabetes is poor medication adherence and persistence. Key contributors to adherence include perceived efficacy, hypoglycemia, weight gain, treatment complexity, convenience, cost, patient beliefs about medications, and trust in the healthcare provider.[97] Therefore, it is crucial to assess adherence and barriers to adherence at every visit and include the patient in the decision-making process. Simplifying the treatment regimen may improve adherence and glycemic control. Fixed-dose combination products may be one way to simplify treatment and have been shown to improve adherence and glycemic control.[98,99]

Therapeutic Inertia

⑮ Another contributing factor to uncontrolled diabetes is therapeutic inertia, which is the failure to initiate or intensify therapy in a timely manner according to evidence-based clinical guidelines. Several studies have shown that it often takes years before treatment is intensified in patients with uncontrolled diabetes. There are multiple reasons for therapeutic inertia including barriers at the patient, provider, and system level. Given the risk of development or progression of diabetes-related complications during treatment delays, it is vital that clinicians combat therapeutic inertia by routinely monitoring patients with DM and taking action in those who are not achieving therapeutic targets.[100]

CONCLUSION

⑯ DM is a heterogeneous group of metabolic disorders which all have elevated BG as their defining characteristic. Achieving good glycemic control, although important, is but one ingredient to optimal health outcomes in patients with diabetes. A comprehensive plan of care should include not only pharmacological and nonpharmacological strategies to lower BG but also methods to screen, prevent, and manage microvascular and macrovascular complications. Current Health Plan Employer Data and Information Set (HEDIS), performance measures annually reported by the National Committee for Quality Assurance (NCQA), recognizes that quality care to patients with diabetes must address glycemia, blood pressure control, statin use, and recommended screening exams.[12] Diabetes is a life-long disease, and patients with diabetes need ongoing support through an interprofessional, team-based approach to care. Adjustments to diet, exercise, and pharmacologic therapies are frequently needed. Clinical inertia should be avoided, and treatment intensification should be implemented if treatment goals have not been met. Patients should receive follow-up care every 3 months, but more frequent follow-up may be necessary if treatment changes have been made. The A1C should be measured every 3 to 6 months, even in patients who are stable on a therapeutic regimen and meeting treatment goals. Identifying and mitigating CV risks—particularly high blood pressure, dyslipidemia, and tobacco use—is critical. Blood pressure should be measured at every encounter and, in patients with elevated blood pressure, home blood pressure monitoring is strongly encouraged. A fasting lipid profile should be obtained as part of an initial assessment and to determine if statin therapy has adequately reduced LDL cholesterol. Performing foot examinations at each face-to-face visit and obtaining a dilated eye examination at least once a year are also important. People with diabetes should receive the influenza vaccine every year and the pneumococcal vaccines and the hepatitis B vaccine series per Center for Disease Control and Prevention recommendations. Using an integrated electronic health record, standardized progress notes, and flow sheets can assist the clinician to determine whether the patient has met these standards of care. As with many chronic diseases, adherence to dietary recommendations, physical activity, and medications is a challenge for most patients. Frequent follow-up, patient education, and positive family engagement can help patients with diabetes lead healthier, happier lives.

ABBREVIATIONS

AACE	American Association of Clinical Endocrinologists
AADE	American Association of Diabetes Educators
ADA	American Diabetes Association
A1C	hemoglobin A1C
ASCVD	atherosclerotic cardiovascular disease
BG	blood glucose
BP	blood pressure
BMI	body mass index
CDCES	Certified Diabetes Care and Education Specialist
CF	correction factor
CGM	continuous glucose monitor
CHD	coronary heart disease
C:I	carbohydrate to insulin ratio

CKD	chronic kidney disease
CSII	continuous subcutaneous insulin infusion
CV	cardiovascular
CVD	cardiovascular disease
DKA	diabetic ketoacidosis
DPP-4	dipeptidyl peptidase-4
DM	diabetes mellitus
DSME/S	diabetes self-management education/support
eGFR	estimated glomerular filtration rate
ESKD	end-stage kidney disease
FDA	Food and Drug Administration
FFA	free fatty acid
FPG	fasting plasma glucose
GDM	gestational diabetes
GI	gastrointestinal
GIP	glucose-dependent insulinotropic polypeptide
GLP-1	glucagon-like peptide-1
GLP-1 RA	glucagon-like peptide-1 receptor agonist
GU	genitourinary
HDL-C	high-density lipoprotein cholesterol
HF	heart failure
HHS	hyperglycemic hyperosmolar syndrome
ICAs	islet cell autoantibodies
ICU	intensive care unit
IFG	impaired fasting glucose
IGT	impaired glucose tolerance

IV	intravenous
LADA	latent autoimmune disease in adults
LDL-C	low-density lipoprotein cholesterol
MDI	multiple daily injections
MNT	medical nutrition therapy
MODY	mature-onset diabetes in the young
NPH	neutral protamine Hagedorn
OGTT	oral glucose tolerance test
PAI-1	plasminogen activator inhibitor-1
PK/PD	pharmacokinetic/pharmacodynamic
POC	point of care
PPAR-γ	peroxisome proliferator activator receptor-γ
PPG	postprandial glucose
SC	subcutaneous
SGLT-2	sodium-glucose co-transporter 2
SMBG	self-monitoring of blood glucose
SU	sulfonylurea
TZD	thiazolidinedione
UGE	urinary glucose excretion
VAT	visceral adipose tissue
XR	extended-release

SELF-ASSESSMENT QUESTIONS

1. Which of the following best describes the biochemical derangements and clinical features associated with type 1 diabetes mellitus?

   A. Hyperinsulinemia, ketosis-prone, patients usually present with hypoglycemia

   B. Insulin resistance, loss of phase 1 insulin release, most commonly develops in older adults

   C. Low C-peptide concentrations, beta cell destruction, most commonly develops in adolescents

   D. High postprandial GLP-1 levels, obesity, patients usually present with no or only mild symptoms

2. All of the following are commonly observed in patients with type 2 diabetes mellitus EXCEPT:

   A. Declining β-cell mass

   B. Reduced hepatic glucose output

   C. Increased postprandial glucagon release

   D. Diminished incretin hormone release following meals

3. Which of the following would meet the diagnostic criteria for diabetes mellitus?

   A. A fasting plasma glucose of 119 mg/dL (6.6 mmol/L)

   B. A hemoglobin A1C value of 6.6% (0.066; 49 mmol/mol)

   C. A plasma glucose of 181 mg/dL (10.0 mmol/L) at 2 hours during a 75-g oral glucose tolerance test (OGTT)

   D. A random plasma glucose of 192 mg/dL (10.7 mmol/L) after a meal; the patient reports no symptoms and gained 5 lb (2.3 kg) over the last 6 months

4. A 20-year-old obese male is newly diagnosed with diabetes mellitus. His father (now age 53) was diagnosed with diabetes when he was 44 years old during a routine physical exam. His only sibling, his sister (now age 25) was diagnosed with impaired fasting glucose when she was 19 years old. His father achieved good glycemic control using two oral agents for several years but last year he required insulin therapy to achieve his glycemic goals. His sister began exercising and lost more than 40 lb (18 kg) after learning her blood glucose was abnormal. Her most recent fasting blood glucose reading was 93 mg/dL (5.2 mmol/L) and her A1C was 5.4% (0.054; 36 mmol/mol). What is the most likely etiology of their diabetes mellitus?

   A. Type 1 DM

   B. Type 2 DM

   C. Mature-onset diabetes in the young (MODY)

   D. Latent autoimmune diabetes in adults (LADA)

5. A patient with type 2 diabetes mellitus with insulin resistance is currently using a total daily dose of 320 units of insulin per day. The patient's last A1C measured this week was 7.8% (0.078; 62 mmol/mol). The patient is being transitioned to a concentrated insulin product. Which of the following would be the most appropriate treatment plan?

   A. Switch to U-300 insulin glargine: inject 240 units subcutaneously daily (given as three injections of 80 units each once daily)

   B. Switch to U-200 insulin lispro: inject 160 units subcutaneously twice daily (given as two injections of 80 units each twice daily)

   C. Switch to U-200 insulin degludec: inject 180 units subcutaneously twice daily (given as two injections of 90 units each twice daily)

   D. Switch to U-500 regular human insulin: inject 100 units subcutaneously three times daily before meals (given as one injection of 100 units each three times a day)

6. All of the following are potential effects associated with sodium-glucose cotransporter-2 inhibitors (SGLT-2 inhibitors) use *EXCEPT*:

   A. Heart failure

   B. Weight loss

   C. Dizziness/lightheadedness

   D. Genitourinary infections

7. GLP-1 receptor agonists lower glucose levels by all of the following physiologic actions *EXCEPT*:

   A. Increase glucose-dependent insulin secretion

   B. Decrease inappropriate glucagon secretion

   C. Slow gastric emptying

D. Increase urinary glucose excretion

8. A 110-kg patient with type 2 diabetes mellitus is taking insulin glargine 82 units at bedtime and scheduled doses of 12 units of insulin apart three times a day before each meal plus additional correction doses of insulin aspart for hyperglycemia. The patient's BGs have consistently been in the 70-90 mg/dL (3.9-5.0 mmol/L) range in the morning before breakfast, pre-evening meal glucose is 100-130 mg/dL (5.6-7.2 mmol/L), and bedtime blood glucose (BG) readings between 200 and 250 mg/dL (11.1 and 13.9 mmol/L). The patient's A1C is currently 7.6% (0.076; 60 mmol/mol) with a goal less than 7% (0.07; 53 mmol/mol). The *next best* step would be to:

   A. Give 6 units of insulin lispro at bedtime.

   B. Increase the dose of insulin lispro before the evening meal.

   C. Change the timing of the insulin glargine injection from bedtime to morning.

   D. Increase the dose of insulin glargine by 10%. Continue to inject subcutaneously at bedtime.

9. An obese patient (weight = 104kg, BMI = 36.2 kg/m^2) with type 2 diabetes mellitus is taking 76 units of insulin degludec daily and insulin glulisine 18 units prior to each meal. Which of the following would be the most appropriate to determine a correction dose to treat hyperglycemia?

   A. 1 extra unit of insulin glulisine will lower blood glucose by 6 mg/dL (0.3 mmol/L).

   B. 1 extra unit of insulin glulisine will lower blood glucose by 14 mg/dL (0.8 mmol/L).

   C. 1 extra unit of insulin glulisine will lower blood glucose by 25 mg/dL (1.4 mmol/L).

   D. 1 extra unit of insulin glulisine will lower blood glucose by 60 mg/dL (3.3 mmol/L).

10. Which one of the following insulin products have a duration of action greater than 24 hours?

   A. Insulin degludec (U-200)

   B. Insulin glulisine (U-100)

   C. Regular human insulin (U-500)

   D. Neutralize protamine Hagedorn insulin (U-100)

11. A patient with type 2 diabetes has adopted several lifestyle changes. He has lost 15 lb (6.8 kg) in the past 3 months. All lab work, vital signs, and physical examination findings are normal except for mild nonproliferative retinopathy and chronic kidney disease (eGFR consistently between 35 and 50 mL/min/1.73 m^2 for the past year) with albuminuria. The patient's A1C today is 6.2% (0.062; 44 mmol/mol). The patient's current treatment regimen includes metformin 500 mg BID with meals, lisinopril 40 mg daily, rosuvastatin 20 mg daily. Which of the following medication changes should be recommended today?

   A. Start dapagliflozin

   B. Discontinue metformin

   C. Discontinue Lisinopril

   D. Increase metformin dose

12. A patient is prescribed metformin 500 mg BID. She states she was diagnosed with gestational diabetes mellitus (GDM) but wants to avoid taking insulin. Which of the following is the most appropriate action to take at this time?

   A. Switch metformin to the extended-release product because it is much better tolerated in pregnancy.

B. Call the prescriber to ask if metformin can switch to glyburide because it has more data in pregnancy.

C. Call the prescriber to switch metformin to human insulin because it is the only FDA-approved treatment option.

D. Make certain the patient is aware that metformin is not currently the drug of choice to treat gestational diabetes.

13. GM is a 59-year-old female here for evaluation of her diabetes. All labs are normal except that her A1C is currently 8.6% (0.086; 70 mmol/mol), vitals are normal, and weight is 196 lb (89 kg; BMI is 34 kg/m^2). Her goal A1C is less than 7.5% (0.075; 58 mmol/mol). She is currently taking metformin 1,000 mg twice daily and canagliflozin 300 mg daily. She has hypertension (current blood pressure is 134/78 mm Hg) and dyslipidemia (current LDL-C is 82 mg/dL [2.12 mmol/L]). She is engaged in regular physical activity most days and avoids simple carbohydrates. Which of the following treatment options would likely have the greatest therapeutic benefits for this patient?

A. Linagliptin 5 mg orally daily

B. Glimepiride 4 mg orally daily

C. Semaglutide 0.25 mg subcutaneously weekly for 4 weeks then 0.5 mg weekly

D. Levemir 20 units subcutaneously at bedtime and titrate dose to achieve fasting blood glucose less than 90 mg/dL (5.0 mmol/L)

14. A 60-year-old overweight patient presents for diabetes follow-up. He has had type 2 diabetes for 10 years and also has hypertension and newly diagnosed peripheral vascular disease. His A1C is currently 7.6% (0.076; 60 mmol/mol) with a goal less than 7% (0.07; 53 mmol/mol). His current medications include metformin 1,000 mg twice daily, lisinopril 20 mg once daily, and amlodipine 10 mg once daily. Which of the following treatment options would likely have the greatest therapeutic benefit for this patient?

A. Dulaglutide

B. Glyburide

C. Insulin glargine U-100

D. Sitagliptin

15. An 84-year-old female has a history of type 2 diabetes, hypertension, dyslipidemia, coronary heart disease, heart failure (NYHA Class 2), and osteoarthritis in the hands, hips, and knees. She resides in an assisted-living facility because she requires assistance with meal preparation and is at high risk for falls. She has some age-related forgetfulness but does not have any significant cognitive impairments. She is currently taking metformin 500 mg twice daily, sitagliptin 50 mg daily, and insulin glargine 20 units daily. Her current A1C is 9.6% (0.096; 81 mmol/mol). Which of the following is the most appropriate goal A1C for this patient?

A. A1C less than 6.5% (0.065; 48 mmol/mol)

B. A1C less than 7% (0.07; 53 mmol/mol)

C. A1C less than 8% (0.08; 64 mmol/mol)

D. A1C less than 10% (0.10; 86 mmol/mol)

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Type 1 diabetes is caused by an autoimmune process that destroys the β-cells in the pancreas, resulting in an absolute insulin deficiency. C-peptide, created by the cleavage of proinsulin, is a marker of endogenous insulin production. Therefore, C-peptide serum concentrations are very low or zero in patients with type 1 diabetes. While type 1 diabetes can occur at any age, it most commonly develops in childhood, with the peak incidence occurring in the early adolescent years prior to puberty (10-14 years old). See "Clinical Presentation" section.

2. **B.** Patients with type 2 diabetes have excessive hepatic glucose production, which is driven by inappropriate glucagon release (Answer C) and

diminished sensitivity to insulin in the liver. Patients with type 2 diabetes have declining β-cell mass over time and typically have less than 50% of normal β-cell mass at the time of diagnosis (Answer A). Diminished incretin normal release following meals (Answer D) is commonly seen in patients with type 2 diabetes. See "Etiology and Pathophysiology" section.

3. **B.** The diagnosis of diabetes mellitus is based on evidence of abnormal plasma glucose concentrations. A hemoglobin A1C greater than 6.5% (0.065; 48 mmol/mol) is considered diagnostic for diabetes mellitus and suggests the patient's plasma glucose has been, on average, greater than 135 mg/dL (7.5 mmol/L) over the preceding 3 months. A fasting glucose reading above 124 mg/dL (6.9 mmol/L), measured on two separate occasions, also indicates the patient has diabetes. An OGTT can be used to diagnose diabetes as well, but the reading at 2 hours must be greater than 200 mg/dL (11.1 mmol/L) to be diagnostic for diabetes. While a random plasma glucose reading following a meal greater than 140 mg/dL (7.8 mmol/L) is abnormal, it is not sufficiently elevated to be diagnostic of diabetes. A random glucose reading must exceed 200 mg/dL (11.1 mmol/L), and the patient must also exhibit classic symptoms of diabetes such as polyuria, polydipsia, or weight loss. See Table 94-4.

4. **B.** This patient is most likely to have type 2 diabetes. Although genetics also influence the development of type 1 diabetes, it is far less inheritable than type 2 diabetes. Given there are multiple family members diagnosed with diabetes, there appears to be a strong inherence pattern that is suggestive of type 2 diabetes, MODY, or LADA. Given that the patient's father was able to use oral anti-diabetes medications for several years to achieve good glycemic control, it indicates that he does not have type 1 DM or LADA. Likewise, given that his sister has been able to achieve good glycemic control with weight loss and regular physical activity without medications, it suggests insulin resistance is a major component of this inheritable cause of diabetes and, thus, it is unlikely to be type 1 DM or LADA. While MODY is a possible etiology of diabetes, the fact that his father was diagnosed at age 44 years old makes this a less likely cause. MODY is generally diagnosed in early adulthood and generally does not require insulin therapy. See "Etiology and Pathophysiology" section.

5. **D.** Based on the patient's daily insulin requirements (>300 units/day), switching to a concentrated insulin product can reduce the number of injections required each day and may lead to improved glycemic control. U-500 insulin, given in two or three divided daily doses, can be used in place of both basal and prandial insulins. If the patient is near the glycemic goal, the total daily dose of insulin is typically reduced by 5% to 10% and re-titrated to achieve good glycemic control. Using insulin lispro (Answer B) would be inappropriate because it is a rapid-acting insulin given to reduce the postprandial glucose surge that occurs after meals and would do little to address basal insulin needs. The dose of insulin glargine (Answer A) would be insufficient to control this patient's blood glucose (in the absence of a prandial insulin), and, as monotherapy, it would not cover prandial insulin needs. The dose of insulin degludec (Answer C) is likely excessive, and, as monotherapy, it would not cover prandial insulin needs.

6. **A.** While some medication classes are associated with the development of heart failure (eg, thiazolidinediones, dipeptidyl peptidase-4 inhibitors), the SGLT-2 inhibitors appear to protect patients against the development of heart failure. Modest weight loss is a common and expected effect of the SGLT-2 inhibitors. Although uncommon, dizziness or lightheadedness can occur if a patient develops orthostatic hypotension due to vascular volume loss. Genitourinary tract infections, including urinary tract infections and candidiasis, were reported in 3% to 5% of patients who used an SGLT-2 inhibitor in clinical trials.

7. **D.** The GLP-1 receptor agonists mimic the action of endogenous GLP-1. They stimulate insulin secretion from pancreatic β-cells in a glucose-dependent manner. In addition, during hyperglycemia, GLP-1 RAs reduce inappropriately elevated levels of glucagon, which results in decreased hepatic glucose output. These agents also have a direct effect on the stomach through the autonomic nervous system to slow gastric emptying, thereby reducing meal-related glucose excursions. Additionally, agents that penetrate the blood-brain barrier increase satiety via the central nervous system. These actions result in a reduction in both glucose and weight. GLP-1 RAs also potentially preserve pancreatic β-cell function and protect against cytokine-induced apoptosis. They do not act on the kidney. The SGLT-2 inhibitors increase urinary glucose excretion.

8. **B.** Given that the patient's blood glucose is elevated at bedtime but is within acceptable ranges in the morning and prior to dinner meal, the best strategy is to increase the prandial insulin dose prior to the evening meal. While administering a dose of rapid-acting insulin at bedtime would "correct" the elevated glucose readings, it does not prevent hyperglycemia, and it may lead to nocturnal hypoglycemia, overcorrecting the elevated blood glucose while the patient is sleeping. Changing the insulin glargine dose from bedtime to morning is unlikely to have the desired effect as the effects of insulin glargine typically last 20 to 24 hours and largely impact fasting glucose readings. Increasing the dose of insulin glargine would potentially result in nocturnal hypoglycemia as the patient's pre-breakfast fasting glucose readings are already within the goal range.

9. **B.** The patient is currently taking 130 units of insulin per day. The total daily dose of insulin is determined by adding all insulin doses administered. In this case, the patient is taking 76 units of insulin degludec plus 18 units of insulin glulisine prior to each meal or 54 units, for a total of 130 units. To

estimate the correction or sensitivity factor, many practitioners use the rule of 1,800 when rapid-acting insulin is used for correction doses. To calculate the sensitivity factor, 1,800 is divided by the total daily dose of insulin (130 units). 1,800/130 = 13.8 or, rounding up, 14. Thus, 1 unit of insulin is anticipated to lower the blood glucose by approximately 14 mg/dL (0.8 mmol/L).

10. **A.** The duration of effect for insulin degludec is consistently greater than 24 hours. Insulin glulisine is a rapid-acting insulin with a typical duration of effect of around 5 to 6 hours. Regular U-500 human insulin has a duration of effect similar to NPH insulin—approximately 12 to 14 hours. See Table 94-7.

11. **A.** Dapagliflozin and other SGLT-2 inhibitors are effective at slowing the progression of CKD in patients with eGFR levels less than 60 mL/min/1.73 m^2 and/or albuminuria. The ADA guidelines recommend initiating an SGLT-2 inhibitor in this patient population independent of A1C, target A1C, or metformin use. Metformin can be used in patients with an eGFR less than 45 mL/min/1.73 m^2 with close monitoring of kidney function but should be discontinued if the eGFR drops below 30 mL/min/1.73 m^2. Some expert recommendations suggest using a lower dose (eg, 500 mg twice daily) in this setting. Based on the current A1C and kidney function, an increased dose is not warranted. Lisinopril is commonly used in patients with kidney insufficiency, but kidney function must be monitored regularly to be certain the serum creatinine does not change significantly (>30% increase) after treatment initiation or dose change. In this case, there would be no reason to discontinue therapy. Rosuvastatin can be safely used in patients with kidney impairment.

12. **D.** Insulin therapy is the drug-of-choice to control blood glucose in women with gestational diabetes. There is limited but reasonably compelling data demonstrating that metformin is safe and effective to use in pregnant women. It is unknown if the potential for fetal harm is greater with metformin use when compared to insulin therapy. There is no compelling reason to switch metformin to glyburide, and the risk of maternal hypoglycemia would be greater with glyburide use. While some patients tolerate the extended-release formulation better than the immediate-release product, pregnant women do not appear to be any more or less likely to tolerate the immediate-release product when compared to other populations. While it is true insulin is the only FDA-approved treatment for gestation diabetes, this does not preclude the off-label use of metformin for this indication. However, the patient should be made aware that metformin is not the drug of choice during pregnancy, and the risk of fetal complication is not yet fully understood. See "Pregnant Women" in the "Special Populations" section.

13. **C.** While all of these options would improve this patient's glycemic control, semaglutide (and other GLP-1 receptor agonists) is more likely to promote weight loss. Basal insulin (insulin detemir) can be titrated to goal and thus would be the best option in a patient with very poor glycemic control (eg, A1C >10.0% [0.10; 86 mmol/mol]). Unfortunately, baseline insulin can promote weight gain and cause hypoglycemia. Linagliptin, while it is weight neutral, is less potent in terms of lower blood glucose and is unlikely to get this patient to goal. Glimepiride is associated with weight gain and hypoglycemia; thus, it is a less attractive option for this patient.

14. **A.** This patient has uncontrolled diabetes with an A1C of 7.9% (0.079; 63 mmol/mol), so additional glucose-lowering medication is warranted. He also has established ASCVD (peripheral vascular disease) and is overweight. A GLP-1 receptor agonist would be the most appropriate treatment option as it has good glucose-lowering efficacy, induced weight loss, and has evidence of reducing major adverse cardiovascular events in patients with established ASCVD. Insulin and sulfonylureas such as glyburide can cause weight gain. Sitagliptin, a DPP-4 inhibitor, is weight neutral. In addition, none of those options have CV benefits.

15. **C.** In older adults with multiple comorbidities, relaxed glycemic goals are appropriate. Thus, an A1C goal of 8.0% (0.080; 64 mmol/mol) would be appropriate for this patient. If this patient had significant cognitive impairments or a life-limiting illness (eg, malignancy, NYHA Class 4 heart failure), reliance on an A1C is no longer recommended, and routine BG monitoring should be used instead with a goal of maintaining the BG between 100 and 180 mg/dL (5.6 and 10.0 mmol/L) throughout the day. An A1C goal greater than 9.0% (0.090; 75 mmol/mol) would likely cause the patient to have significant symptoms such as frequent urination as well as increase the risk of falls due to orthostatic hypotension and urinary tract infections due to glycosuria. A more aggressive A1C goal of less than 7% or 6.5% (0.070 or 0.065; 53 or 48 mmol/mol) is unlikely to provide long-term benefits to this patient and would increase her risk of hypoglycemia which is more difficult to detect in older adults and may accelerate cognitive decline. See Table 94-6 for Goals of Therapy.

Chapter 96: Thyroid Disorders

Michael P. Kane; Gary Bakst

KEY CONCEPTS

KEY CONCEPTS

① Thyrotoxicosis is most commonly caused by Graves' disease, which is an autoimmune disorder in which thyroid-stimulating antibody (TSAb) directed against the thyrotropin receptor elicits the same biologic response as thyroid-stimulating hormone (TSH).

② Hyperthyroidism may be treated with antithyroid drugs such as methimazole (MMI) or propylthiouracil (PTU), radioactive iodine (RAI: sodium iodide-131 [^{131}I]), or surgical removal of the thyroid gland; selection of the initial treatment approach is based on patient characteristics such as age, concurrent physiology (eg, pregnancy), comorbidities (eg, chronic obstructive lung disease), and convenience.

③ MMI and PTU reduce the synthesis of thyroid hormones and are similar in efficacy, although their dosing ranges differ by 20-fold. Overall, PTU has a greater incidence of side effects. Agranulocytosis is a rare but severe adverse effect associated with both medications.

④ Response to MMI and PTU is seen in 4 to 6 weeks and therefore β-blocker therapy may be concurrently initiated to reduce adrenergic symptoms. Maximal response is typically seen in 4 to 6 months; treatment usually continues for 1 to 2 years, and therapy is monitored by clinical signs and symptoms and by measuring the serum concentrations of TSH and free thyroxine (FT_4).

⑤ Adjunctive therapy with β-blockers controls the adrenergic symptoms of thyrotoxicosis but does not correct the underlying disorder; iodine may also be used adjunctively in preparation for surgery and acutely for thyroid storm.

⑥ Many patients choose to have ablative therapy with ^{131}I rather than undergo repeated courses of MMI or PTU treatment; most patients receiving RAI eventually become hypothyroid and require thyroid hormone supplementation.

⑦ Hypothyroidism is most often due to an autoimmune disorder known as *Hashimoto's thyroiditis*.

⑧ The drug of choice for replacement therapy in hypothyroidism is levothyroxine.

⑨ Studies of combination therapy with levothyroxine and liothyronine have not shown reproducible benefits. This approach to the treatment of hypothyroidism requires further study.

⑩ Monitoring of levothyroxine replacement therapy is achieved by observing clinical signs and symptoms and by measuring the serum TSH level. An elevated TSH indicates under-replacement; a suppressed TSH indicates over-replacement.

INTRODUCTION

Thyroid hormones affect the function of virtually every organ system. In a child, thyroid hormone is critical for normal growth and development. In an adult, the major role of thyroid hormone is to maintain metabolic stability. Substantial reservoirs of thyroid hormone in the thyroid gland and blood provide constant thyroid hormone availability. In addition, the hypothalamic-pituitary-thyroid axis is exquisitely sensitive to small changes in circulating thyroid hormone concentrations, and alterations in thyroid hormone secretion maintain peripheral free thyroid hormone levels within a narrow range. Patients seek medical attention for evaluation of symptoms due to abnormal thyroid hormone levels or because of diffuse or nodular thyroid enlargement.

Thyroid Hormone Synthesis

The thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) (Fig. 96-1) are formed within thyroglobulin (TG), a large glycoprotein synthesized in the thyroid cell. Because of the unique tertiary structure of this glycoprotein, iodinated tyrosine residues present in TG are able to bind together to form active thyroid hormones.

Iodide is actively transported through the basolateral membrane via a Na^+/I^- symporter from the extracellular space into the thyroid follicular cell against an electrochemical gradient, driven by the coupled transport of sodium.[1] Structurally related anions such as thiocyanate (SCN^-), perchlorate (ClO_4^-), and pertechnetate (TcO_4^-) are competitive inhibitors of iodine transport.[1] In addition, bromine, fluorine, and, under certain circumstances, lithium block iodide transport into the thyroid (Table 96-1). Inorganic iodide that enters the thyroid follicular cell is ushered through the cell to the apical membrane, where it is transported into the follicular lumen by pendrin, and possibly other transport proteins.[1] Located on the luminal side of the apical membrane, thyroid peroxidase oxidizes iodide and covalently binds the organified iodide to tyrosine residues within TG (Fig. 96-2). It is interesting that although salivary glands and the gastric mucosa are able to actively transport iodide, they are unable to effectively incorporate iodide into proteins, given the lack of similar oxidizing machinery.

FIGURE 96-2

Thyroid hormone synthesis. Iodide is transported from the plasma, through the cell, to the apical membrane, where it is organified and coupled to the thyroglobulin (TG) synthesized within the thyroid cell. Hormone stored as colloid re-enters the cell through endocytosis and moves back toward the basal membrane, where thyroxine (T_4) is secreted.

TABLE 96-1

Thyroid Hormone Synthesis and Secretion Inhibitors

Mechanism of Action	Substance
Blocks iodide transport into the thyroid	• Bromine • Fluorine • Lithium
Impairs organification and coupling of thyroid hormones	• Thionamides • Sulfonamide • Salicylamide • Antipyrine
Inhibits thyroid hormone secretion	Iodide (large doses) Lithium

The iodinated tyrosine residues monoiodotyrosine (MIT) and diiodotyrosine (DIT) combine to form iodothyronines (Fig. 96-3). Thus, two molecules of DIT combine to form T_4, whereas MIT and DIT constitute T_3. In addition to its role in iodine organification, the hemoprotein thyroid peroxidase also catalyzes the formation of iodothyronines (coupling).

FIGURE 96-3

Scheme of coupling reactions. After tyrosine is iodinated to form monoiodotyrosine (MIT) or diiodotyrosine (DIT) (organification of the iodine), MIT and DIT combine to form triiodothyronine (T_3) or two molecules of DIT combine to form thyroxine T_4 (coupling).

Iodine deficiency causes an increase in the MIT:DIT ratio in TG and leads to a relative increase in the production of T_3:T_4. Because T_3 is more potent than T_4, the increase in T_3 production in iodine-deficient areas may be beneficial. The thionamide drugs used to treat hyperthyroidism inhibit thyroid peroxidase and thus block thyroid hormone synthesis.

Thyroglobulin is stored in the follicular lumen and must reenter the cell, where the process of proteolysis liberates thyroid hormone into the bloodstream. Thyroid follicles active in hormone synthesis are identified histologically by columnar epithelial cells lining a follicular lumen, which is depleted of colloid. Inactive follicles are lined by cuboidal epithelial cells and are replete with colloid. Both iodide and lithium block the release of preformed thyroid hormone, through poorly understood mechanisms.

T_4 and T_3 are transported in the bloodstream primarily by three proteins: (1) thyroxine-binding globulin (TBG), (2) transthyretin (TTR; also known as TBPA, thyroxine-binding prealbumin), and (3) albumin. It is estimated that 99.96% of circulating T_4 and 99.5% of T_3 are bound to these proteins. However, only the unbound (free) thyroid hormone is able to diffuse into the cell, elicit a biologic effect, and regulate thyroid-stimulating hormone (TSH; also known as *thyrotropin*) secretion from the pituitary. Multiple functions have been ascribed to these transport proteins, including (a) assuring minimal urinary loss of iodide, (b) providing a mechanism for uniform tissue distribution of free hormone, and (c) transporting hormone into the central nervous system (CNS).

Whereas T_4 is secreted solely from the thyroid gland, less than 20% of T_3 is produced in the thyroid. The majority of T_3 is formed from the breakdown of T_4 catalyzed by the 5'-monodeiodinase enzymes found in extrathyroidal peripheral tissues. Because the binding affinity of nuclear thyroid hormone receptors (TRs) is 10 to 15 times higher for T_3 than for T_4, the deiodinase enzymes play a pivotal role in determining overall metabolic activity. Three different monodeiodinase enzymes are present in the body. Of the enzymes that catalyze 5'-monodeiodination, type I enzymes are present in peripheral tissues such as the liver and kidney, whereas type II enzymes are found in the CNS, pituitary, and thyroid. Type III enzymes, found in the placenta, skin, and developing brain, inactivate T_4 and T_3 by deiodinating the inner ring at the 5 position. The principal characteristics of these enzymes are listed in Table 96-2. T_4 may also be acted on by the enzyme 5'- monodeiodinase to form reverse T_3, but this accounts for a small component of hormone metabolism. Polymorphisms in the deiodinase genes may prove to be of clinical significance. For example, a polymorphism in the type I deiodinase leading to increased activity seems to be associated with an increased circulating ratio of free T_3 to free T_4.[2] Reverse T_3 has no known biological activity. T_3 is removed from the body by deiodinating degradation and through the action of sulfotransferase enzyme systems converting to T_3 sulfate and 3,3-diiodothyronine sulfates, thus facilitating enterohepatic clearance. Thyronamines are derivatives of thyroid hormones that are present in low concentrations in human serum. The most studied thyronamine, 3-iodothyronamine, can theoretically be made from T_4 by decarboxylation and deiodination. Administration of pharmacologic amounts of 3-iodothyronamine to animals has profound effects on temperature regulation and cardiac function and shifts fuel metabolism from carbohydrates to lipids. However, a possible physiologic role for thyronamines has yet to be determined, although altered levels may be associated with some disease states.

TABLE 96-2

Properties of Iodothyronine 5′-Deiodinase Isoforms

Property	Type I	Type II	Type III
Susceptibility to propylthiouracil	High	Low	Low
Tissue localization	Thyroid, liver, kidney	Pituitary, thyroid, CNS, brown adipose tissue	Placenta, developing brain, skin
Preferred substrate	rT_3 and T_3	T_4 and rT_3	T_3 and T_4
Physiologic or pathophysiologic role	Clearance of rT_3 and T_3, the predominant extrathyroidal source of T_3 in hyperthyroidism	Intracellular T_3 production, especially for the brain in hypothyroidism or iodine deficiency, and maintenance of plasma T_3	Clearance of T_3 and T_4
Developmental expression	Expressed latest in development; predominant deiodinase in adult	Expressed second; especially high in brain and brown adipose tissue	Expressed first; high in developing brain; may be important for fetal thyroid hormone metabolism

rT_3, reverse T_3; T_3, triiodothyronine; T_4, thyroxine.

Thyroid Hormone Regulation and Action

The growth and function of the thyroid are stimulated by activation of the thyrotropin receptor by TSH.[3] The receptor belongs to the family of G-protein–coupled receptors. The thyrotropin receptor is coupled to the α subunit of the stimulatory guanine-nucleotide–binding protein (Gsα), activating adenylate cyclase and increasing the accumulation of cyclic adenosine monophosphate. Through this mechanism, TSH stimulates the expression of Na^+/I^- symporter, TG, and thyroid peroxidase genes as well as increases apical iodide efflux. Somatic activating mutations in the receptor are commonly seen in autonomously functioning thyroid nodules.[4] Rarely, germline-activating mutations of the TSH receptor have been reported in kindreds with Leclere syndrome, and thyrotoxicosis can result from germline-activating mutations in G-protein signaling in McCune–Albright syndrome. Conversely, thyrotropin resistance results from point mutations that prevent TSH binding, leading to abnormalities in the thyrotropin receptor–adenylate cyclase system and congenital hypothyroidism.[3] Individuals with this abnormality have high levels of TSH but decreased TG levels and a normal or small thyroid gland.

Thyroid hormone nuclear receptors regulate the transcription of target genes in the presence of physiologic concentrations of T_3.[3] Unlike most other nuclear receptors, TRs also actively regulate gene expression in the absence of hormone, typically resulting in an opposite effect. TRs translocate from the cytoplasm to the nucleus, interact in the nucleus with T_3, and target genes and other proteins required for basal and T_3-dependent gene transcription. TRs exist in several isoforms, including TRβ1, TRβ2, and TRα1.[3] Thyroid hormone has different actions in different tissues based on the tissue-specific expression of the different TR isoforms. There is interest in developing thyroid hormone analogs that selectively activate specific TR isoforms. Such agents could theoretically have targeted desirable effects such as stimulating energy expenditure without having adverse effects on other tissues.[5]

The production of thyroid hormone is regulated in two main ways. First, thyroid hormone is regulated by TSH secreted by the anterior pituitary. The secretion of TSH is itself under negative feedback control by the circulating level of free thyroid hormone and the positive influence of hypothalamic thyrotropin-releasing hormone (TRH). Second, extrathyroidal deiodination of T_4 to T_3 is regulated by a variety of factors including nutrition, nonthyroidal hormones, ambient temperatures, drugs, and illness.

HYPERTHYROIDISM AND THYROTOXICOSIS

Thyrotoxicosis results when tissues are exposed to excessive levels of T_4, T_3, or both.[6] Hyperthyroidism, which is one cause of thyrotoxicosis, refers specifically to overproduction of thyroid hormone by the thyroid gland.

EPIDEMIOLOGY—THYROTOXICOSIS

In the National Health and Nutrition Examination Survey (NHANES) III, 0.7% of those surveyed who were not taking thyroid medications and had no history of thyroid disease had subclinical hyperthyroidism (TSH less than 0.1 mIU/L, and T_4 normal), and 0.5% had “clinically significant” hyperthyroidism (TSH less than 0.1 mIU/L, and T_4 more than 13.2 mcg/dL [170 nmol/L]).[7] The prevalence of suppressed TSH values peaks in people aged 20 to 39, declines in those 40 to 79, and increases again in those 80 or older. Abnormal TSH levels were more common among women than among men.

ETIOLOGY AND PATHOPHYSIOLOGY—THYROTOXICOSIS

If the clinical history and examination do not provide pathognomonic clues to the etiology of the patient’s thyrotoxicosis, measurement of the radioactive iodine uptake (RAIU) is critical in the evaluation (Table 96-3). The normal 24-hour RAIU ranges from 10% to 30% with some regional variation that is due to differences in iodine intake. An elevated RAIU indicates endogenous hyperthyroidism; that is, the patient’s thyroid gland is actively overproducing T_4, T_3, or both. Conversely, a low RAIU in the absence of iodine excess indicates that high levels of thyroid hormone are not a consequence of thyroid gland hyperfunction but are likely due to thyroiditis or hormone ingestion. The importance of differentiating endogenous hyperthyroidism from other causes of thyrotoxicosis lies in the widely different prognosis and treatment of the diseases in these two categories. Therapy of thyrotoxicosis associated with thyroid hyperfunction is mainly directed at decreasing the rate of thyroid hormone synthesis, secretion, or both. Such measures are ineffective in treating thyrotoxicosis that is not the result of endogenous hyperthyroidism because hormone synthesis and regulated hormone secretion are already at a minimum.

Causes of Thyrotoxicosis Associated with Suppressed RAIU

Subacute Thyroiditis

Painful subacute (granulomatous or de Quervain) thyroiditis often develops after a viral syndrome, but rarely has a specific virus been identified in thyroid parenchyma. A genetic predisposition exists, with a markedly higher risk for developing subacute thyroiditis for patients with HLA-Bw35. Systemic symptoms often accompany the syndrome, including fever, malaise, and myalgia, in addition to those symptoms due to thyrotoxicosis. Typically, patients complain of severe pain in the thyroid region, which often extends to the ear on the affected side. With time, the pain may migrate from one side of the gland to the other. On physical examination, the thyroid gland is firm and exquisitely tender. Signs of thyrotoxicosis are present.[17]

Thyroid function tests typically run a triphasic course. Initially, serum T_4 levels are elevated due to the release of preformed thyroid hormone from disrupted follicles. The 24-hour RAIU during this time is less than 2% due to thyroid inflammation and TSH suppression by the elevated T_4 level. As the disease progresses, intrathyroidal hormone stores are depleted, and the patient may become mildly hypothyroid with an appropriately elevated TSH level. During the recovery phase, thyroid hormone stores are replenished, and serum TSH concentration gradually returns to normal. Recovery is generally complete within 2 to 6 months. Most patients remain euthyroid, and recurrences of painful thyroiditis are extremely rare. The patient with painful thyroiditis should be reassured that the disease is self-limited and is unlikely to recur. Thyrotoxic symptoms may be relieved with β-blockers. nonsteroidal anti-inflammatory drugs (NSAIDs) will usually relieve the pain. Occasionally, prednisone (30-40 mg daily) must be used to suppress the inflammatory process. Antithyroid drugs (ATD) are not indicated because they will not be effective as they do not decrease the release of preformed thyroid hormone.

Painless Thyroiditis

Painless (silent and lymphocytic) thyroiditis is a common cause of thyrotoxicosis and may represent up to 15% of cases of thyrotoxicosis in North America. When lymphocytic thyroiditis develops during the first 12 months after the end of pregnancy, the condition is also called *postpartum thyroiditis*. The etiology is not fully understood and may be heterogeneous, but evidence indicates that autoimmunity underlies most cases. There is an increased frequency of HLA-DR3 and DR5 in patients with painless thyroiditis; non-endocrine autoimmune diseases are also more common. Histologically, diffuse lymphocytic infiltration is generally identified. The triphasic course of this illness mimics that of subacute thyroiditis. Most patients present with mild thyrotoxic symptoms. Lid retraction and lid lag are present, but exophthalmos is absent. The thyroid gland may be diffusely enlarged, but thyroid tenderness is absent.

The 24-hour RAIU will typically be suppressed to less than 2% during the thyrotoxic phase of painless thyroiditis. Anti-TG and antithyroid peroxidase antibody (anti-TPOAb) levels are elevated in more than 50% of patients. Patients with mild hyperthyroidism and painless thyroiditis should be reassured that they have a self-limited disease, although patients with postpartum thyroiditis may experience a recurrence of the disease with subsequent pregnancies. As with other thyrotoxic syndromes, adrenergic symptoms may be ameliorated with propranolol or metoprolol. ATDs, which inhibit new hormone synthesis, are not indicated because they do not decrease the release of preformed thyroid hormone. A small proportion of patients may have recurrent episodes of thyroiditis or may develop permanent hypothyroidism.[17]

Exogenous Thyroid Hormone

Thyrotoxicosis factitia is hyperthyroidism due to ingestion of thyroid hormone. This category includes hyperthyroidism produced by the intentional ingestion of exogenous thyroid hormone. Obesity is the most common non-thyroidal disorder for which thyroid hormone is inappropriately used, but thyroid hormone has been used for almost every conceivable problem from menstrual irregularities and infertility to hypercholesterolemia and baldness. There is little evidence to suggest that treatment with thyroid hormone is beneficial for any of these conditions in euthyroid individuals.[18] Thyrotoxicosis factitia can also occur when too large a dose of thyroid hormone is used to treat conditions in which it is likely to be beneficial, such as differentiated thyroid carcinoma. In addition to this iatrogenic cause, thyrotoxicosis factitia may occur after accidental pediatric ingestion or pharmacy error. Thyrotoxicosis factitia may also be caused by the purposeful and secretive ingestion of thyroid hormone by patients (usually with a healthcare background) who wish to obtain attention or lose weight.

Thyroid hormone may also be accidentally ingested in food sources. Reports of thyrotoxicosis in Minnesota and Nebraska in the 1980s were attributed to ingestion of ground beef contaminated by bovine thyroid glands. More recently thyrotoxicosis due to porcine thyroid tissue in meat products has been reported in Spain and Uruguay.

Thyrotoxicosis factitia should be suspected in a thyrotoxic patient without evidence of increased hormone production, thyroidal inflammation, or ectopic thyroid tissue. The RAIU is at low levels because the patient’s thyroid gland function is suppressed by the exogenous thyroid hormone. Measurement of plasma TG is a valuable laboratory aid in the diagnosis of thyrotoxicosis factitia. TG is normally secreted in small amounts by the thyroid gland; however, when thyroid hormone is taken orally, TG levels tend to be lower than the normal range. In other entities characterized by a low RAIU, such as thyroiditis, leakage of preformed thyroid hormone results in elevated TG levels. If a history of thyroid hormone ingestion is elicited or deduced, exogenous thyroid hormone should be withheld for 4 to 6 weeks, and thyroid function tests should be repeated to ensure a euthyroid state has been restored. Rarely, thyroid hormones may be the drug of abuse and detection is difficult with standard thyroid hormone assays. For example, tiratricol (TRIAC), an endogenous metabolite of T_3 that has been used for weight loss and paradoxically by bodybuilders, will suppress TSH at high doses and may cross-react in many T_3 immunoassays; thus, thyrotoxicosis factitia due to tiratricol abuse may be misinterpreted as T_3 toxicosis, and also lead to serious side effects.

Medications Containing Iodine

Amiodarone may induce thyrotoxicosis (2%–3% of patients), overt hypothyroidism (5% of patients), subclinical hypothyroidism (25% of patients), or euthyroid hyperthyroxinemia, depending on the underlying thyroid function and pathology.[19] Because amiodarone contains 37% iodine by weight, approximately 6 mg/day of iodine is released for each 200 mg of amiodarone, 1,000 times greater than the recommended daily amount of iodine of 150 mcg/day. As a result of this iodine overload, iodine-exacerbated thyroid dysfunction commonly occurs among those patients with preexisting thyroid disease: thyrotoxicosis in patients with hyperthyroidism or euthyroid nodular autonomy and hypothyroidism in patients with autoimmune thyroid disease. In contrast to hyperthyroidism with increased synthesis of thyroid hormone induced by amiodarone (type I), destructive thyroiditis with leakage of TG and thyroid hormones also occurs (type II), typically among individuals with otherwise normal glands. The two types of amiodarone-induced thyrotoxicosis may be differentiated using color-flow Doppler ultrasonography. Such distinction is critically important, given the therapeutic implications of the two syndromes: type I amiodarone-induced hyperthyroidism responds somewhat to thionamides, whereas type II may respond to glucocorticoids.[19] Obviously, RAI therapy is inappropriate in type I due to the drug-induced iodine excess, and in type II due to lack of increased hormone synthesis. The manifestations of amiodarone-induced thyrotoxicosis may be atypical symptoms such as ventricular tachycardia and exacerbation of the underlying chronic obstructive pulmonary disease, both of which are significant, given the severe underlying cardiac pathology that led to the use of amiodarone in the first place. Amiodarone also directly interferes with type I 5'-deiodinase, leading to reduced conversion of T_4 to T_3 and hyperthyroxinemia without thyrotoxicosis.[19]

High intake of biotin can interfere with thyroid hormone assays, leading to false results of thyroid function tests.[20,21] Excess biotin leads to falsely elevated results of TT_4, FT_4, and TT_3 (competitive immunoassays), and to falsely low TSH levels (immunometric or sandwich immunoassays). This is not an issue of endogenous interference but an interference with the assay itself. Biotin doses of greater than 5,000 mcg/day are associated with major interference on immunoassays; in such circumstances, it is recommended patients hold their biotin doses for 24 to 48 hours before laboratory testing.

Thyroid Cancer

In widely metastatic differentiated papillary or follicular carcinomas with relatively well-preserved function, sufficient thyroid hormones can be synthesized and secreted to produce thyrotoxicosis. In most instances, a previous diagnosis of thyroid malignancy has been made. The diagnosis can be confirmed by whole-body ^{131}I scanning. Treatment with ^{131}I is generally effective at ablating functioning thyroid metastases.

Struma Ovarii

Struma ovarii is a teratoma of the ovary that contains differentiated thyroid follicular cells and is capable of making thyroid hormones. This extremely rare cause of thyrotoxicosis is suggested by the absence of thyroid enlargement in a thyrotoxic patient with a suppressed RAIU in the neck and no findings to suggest thyroiditis. The diagnosis is established by localizing functioning thyroid tissue in the ovary with whole-body RAI (sodium iodide-131 [^{131}I]) scanning. Interestingly, struma ovarii not associated with hyperthyroidism is much more common than struma ovarii associated with hyperthyroidism. Because the tissue is neoplastic and potentially malignant, combined surgical and radioiodine treatment of malignant struma ovarii for both monitoring and therapy of relapse is the recommended treatment.

Causes of Thyrotoxicosis Associated with Elevated RAIU

Graves' Disease

① Graves' disease is an autoimmune syndrome that usually includes hyperthyroidism, diffuse thyroid enlargement, exophthalmos, and, less commonly, pretibial myxedema and thyroid acropachy (Fig. 96-4).[6,9] Graves' disease is the most common cause of hyperthyroidism, with a prevalence estimated to be 3 per 1,000 population in the United States. Hyperthyroidism results from the action of thyroid-stimulating antibodies (TSAbs), which are directed against the thyrotropin receptor on the surface of the thyroid cell. When these immunoglobulins bind to the receptor, they activate downstream G-protein signaling and adenylate cyclase in the same manner as TSH. Autoantibodies that react with orbital muscle and fibroblast tissue in the skin are responsible for the extrathyroidal manifestations of Graves' disease, and these autoantibodies are encoded by the same germline genes that encode for other autoantibodies for striated muscle and thyroid peroxidase. Clinically, the extrathyroidal disorders may not appear at the same time that hyperthyroidism develops.

FIGURE 96-4

Features of Graves' disease. (*A*) Facial appearance in Graves' disease; lid retraction, periorbital edema, and proptosis are marked. (*B*) Thyroid dermopathy over the lateral aspects of the shins. There is now compelling evidence that heredity predisposes the susceptible individual to the development of clinically overt autoimmune thyroid disease in the setting of appropriate environmental and hormonal triggers. A role for gender in the emergence of Graves' disease is suggested by the fact that hyperthyroidism is approximately eight times more common in women than in men. Other lines of evidence support a role for heredity. First, there is a well-recognized clustering of Graves' disease within some families. Twin studies in Graves' disease have revealed that a monozygotic twin has a 35% likelihood of ultimately developing the disease compared with a 3% likelihood for a dizygotic twin, resulting in an estimation that 79% of the predisposition to Graves' disease is genetic. Second, the occurrence of other autoimmune diseases, including Hashimoto's thyroiditis, is also increased in families of patients with Graves' disease. Third, several studies have demonstrated an increased frequency of certain human leukocyte antigens (HLAs) in patients with Graves' disease. Differing HLA associations have been identified in the various ethnic groups studied. In White patients, for example, the relative risk of Graves' disease in carriers of the HLA-DR3 haplotype is between 2.5 and 5, whereas lesser associations have been reported for HLA-B8 and the HLA-DQA*0501allele. Several gene loci have been associated with autoimmune thyroid diseases such as Graves' disease. It is thought that these susceptibility genes interact with environmental triggers to induce thyroid disease through epigenetic effects.

The thyroid gland is diffusely enlarged in the majority of patients with Graves' disease and is commonly 40 to 60 g (two to three times the normal size). The surface of the gland is either smooth or bosselated, and the consistency varies from soft to firm. For patients with severe disease, a thrill may be felt and a systolic bruit may be heard over the gland, reflecting the increased intraglandular vascularity typical of hyperplasia. Whereas the presence of any of the extrathyroidal manifestations of this syndrome, including exophthalmos, pretibial myxedema, or thyroid acropachy, in a thyrotoxic patient is pathognomonic of Graves' disease, most patients can be diagnosed on the basis of their history and examination of their diffuse goiter (see Fig. 96-4). An important clinical feature of Graves' disease is the occurrence of spontaneous remissions, albeit uncommon. The abnormalities in TSAb production may decrease or disappear over time.

The results of laboratory tests in thyrotoxic Graves' disease include an increase in the overall hormone production rate with a disproportionate increase in T_3 relative to T_4 (Table 96-4). In an occasional patient, the disproportionate overproduction of T_3 is exaggerated, with the result that only the serum T_3 concentration is increased (T_3 toxicosis). The saturation of TBG is increased due to the elevated levels of serum T_4 and T_3. As a result, the concentrations of free T_4 and free T_3 are increased to an even greater extent than are the measured serum total T_4 and T_3 concentrations. The TSH level will be suppressed or undetectable due to negative feedback by elevated levels of thyroid hormone at the pituitary.

TABLE 96-4

Thyroid Function Tests in Different Thyroid Conditions

	Total T_4	Free T_4	Total T_3	TSH
Normal	4.5-10.9 mcg/dL(58-140 nmol/L)	0.8-2.7 ng/dL(10.3-34.7 pmol/L)	60-181 ng/dL(0.92-2.79 nmol/L)	0.5-4.7 mIU/L
Hyperthyroid	↑↑	↑↑	↑↑↑	↓↓[a]
Hypothyroid	↓↓	↓↓	↓	↑↑[a]
Increased TBG	↑	Normal	↑	Normal

[a] Primary thyroid disease.

For the patient with symptomatic disease, measurement of the serum-free T_4 concentration, total T_4, total T_3, and the TSH value will confirm the diagnosis of thyrotoxicosis. For the patient who is not pregnant or lactating, a 24-hour RAIU should be obtained if there is any diagnostic uncertainty, for example, recent onset of symptoms or other factors suggestive of thyroiditis. An increased RAIU indicates that the thyroid gland is inappropriately utilizing the iodine to produce more thyroid hormone at a time when the patient is thyrotoxic.

Thyrotoxic periodic paralysis is a rare complication of hyperthyroidism most commonly observed in Asian and Hispanic populations.[10] It presents as recurrent proximal muscle flaccidity ranging from mild weakness to total paralysis. The paralysis may be asymmetric and usually involves muscle groups that are strenuously exercised before the attack. Cognition and sensory perception are spared, whereas deep tendon reflexes are markedly diminished. The condition is characterized by hypokalemia and low urinary potassium excretion. Hypokalemia results from a sudden shift of potassium from extracellular to intracellular sites rather than reduced total body potassium. High-carbohydrate loads and exercise provoke the attacks. Treatment includes correcting the hyperthyroid state, potassium administration, spironolactone to conserve potassium, and propranolol to minimize intracellular shifts. Some patients with this condition have a mutation in the inwardly rectifying potassium channel Kir2.6.[11]

Toxic Adenoma

An autonomous thyroid nodule is a discrete thyroid mass whose function is independent of pituitary and TSH control. The prevalence of toxic adenoma ranges from about 2% to 9% of thyrotoxic patients and depends on iodine availability and geographic location. Toxic adenomas are benign tumors that produce thyroid hormones. They arise from gain-of-function somatic mutations of the TSH receptor or, less commonly, the Gsα protein; more than a dozen TSH receptor mutations have been described.[6] These nodules may be referred to as *toxic adenomas*, or “hot” nodules, because of their persistent uptake on a radioiodine thyroid scan, despite suppressed uptake in the surrounding non-nodular gland (Fig. 96-5). The amount of thyroid hormone produced by an autonomous nodule is mass related. Therefore, hyperthyroidism usually occurs with larger nodules (ie, those more than 3 cm in diameter). Older patients (older than 60 years) are more likely (up to 60%) to be thyrotoxic from autonomous nodules than are younger patients (12%). There are many reports of isolated elevation of serum T_3 in patients with autonomously functioning nodules. Therefore, if the T_4 level is normal, a T_3 level must be measured to rule out T_3 toxicosis. If autonomous function is suspected but the TSH is normal, the diagnosis can be confirmed by a failure of the autonomous nodule to decrease its iodine uptake during exogenous T_3 administration sufficient to suppress TSH.

Surgical resection, thionamides, percutaneous ethanol injection, and radioactive iodine (RAI) ablation are treatment options, but since thionamides do not halt the proliferative process in the nodule, definitive therapies are recommended. Ethanol ablation may be associated with pain and damage to surrounding extrathyroidal tissues, limiting its acceptance in the United States. It has been hypothesized that sublethal radiation doses received by the surrounding non-nodular thyroid tissue during RAI therapy of toxic nodules may lead to induction of thyroid cancer. However, thyroid cancer has rarely been associated with RAI therapy, and newer studies suggest hyperthyroidism itself, rather than RAI therapy, as being associated with non-thyroid malignancies.[12] There is a modest positive association between the dose of radioactive iodine absorbed into the gland and risk of solid cancer death;[13] however, the same authors later indicated that after controlling for known confounding, there no longer appeared to be a significant association in the risk of solid cancer mortality by treatment group.[14] An autonomously functioning nodule, if not large enough to cause thyrotoxicosis, can often be managed conservatively without therapy.

FIGURE 96-5

Radioiodine thyroid scans. (A) Normal or increased thyroid uptake of iodine-125 (^{125}I). (B) Thyroid with a marked decrease in ^{125}I uptake in a large palpable mass. (C) Increased ^{125}I uptake isolated to a single nodule, the "hot nodule." (D) Decreased thyroid ^{125}I uptake in an isolated region, the "cold nodule." *(Reproduced with permission from Molina PE. Multinodular Goiters

In multinodular goiters (MNGs), follicles with autonomous function coexist with normal or even nonfunctioning follicles. The pathogenesis of MNG is thought to be similar to that of toxic adenoma: diffuse hyperplasia caused by goitrogenic stimuli, leading to mutations and clonal expansion of benign neoplasms. The functional status of the nodule(s) depends on the nature of the underlying mutations, whether activating such as TSH receptor mutations or inhibitory such as RAS mutations. Thyrotoxicosis in an MNG occurs when a sufficient mass of autonomous follicles generates enough thyroid hormone to exceed the needs of the patient. It is not surprising that this type of hyperthyroidism develops insidiously over a period of several years and predominantly affects older individuals with long-standing goiters. The patient's complaints of weight loss, depression, anxiety, and insomnia may be attributed to old age. Any unexplained chronic illness in an elderly patient presenting with an MNG calls for the exclusion of hidden (silent) thyrotoxicosis.[15] Current third-generation TSH assays are able to detect subclinical hyperthyroidism.

A thyroid scan will show patchy areas of autonomously functioning thyroid tissue intermixed with hypofunctioning areas. When the patient is euthyroid, therapy is based on the need to reduce goiter size due to mass-related symptoms such as dysphagia. Doses of thyroid hormone sufficient to suppress TSH levels may slow goiter growth or cause some degree of shrinkage, but, in general, suppression therapy for nodular disease is inadequate to address mass effect. The preferred treatment for toxic MNG is RAI or surgery. Surgery is usually selected for younger patients and patients in whom large goiters impinge on vital organs. Alternatively, percutaneous injection of 95% ethanol has also been used to destroy single or multinodular adenomas with a 5-year success rate approaching 80%.

Trophoblastic Diseases

Human chorionic gonadotropin (hCG) is a stimulator of the TSH receptor and may cause hyperthyroidism. The basis for the thyrotropic effect of hCG is the structural similarity of hCG to TSH (similar α subunits and unique β subunits). For patients with hyperthyroidism caused by trophoblastic tumors, serum hCG levels usually exceed 300 U/mL (kU/L) and always exceed 100 U/mL (kU/L). The mean peak hCG level in normal pregnancy is 50 U/mL (kU/L).

On a molar basis, hCG has only 1/10,000 the activity of pituitary TSH in mouse bioassays. Nevertheless, this thyrotropic activity may be very substantial for patients with trophoblastic tumors, whose serum hCG concentrations may reach 2,000 U/mL (kU/L).

TSH-Induced Hyperthyroidism

To better understand these syndromes, we must first review TSH biosynthesis and secretion. TSH is synthesized in the anterior pituitary as separate α- and β-subunit precursors. The α subunits from luteinizing hormone (LH), follicle-stimulating hormone (FSH), hCG, and TSH are identical, whereas the β subunits are unique and confer immunologic and biologic specificity. Free β subunits are devoid of receptor-binding and biologic activity and require combination with an α subunit to express their activity. Criteria for the diagnosis of TSH-induced hyperthyroidism include (a) evidence of peripheral hypermetabolism, (b) diffuse thyroid gland enlargement, (c) elevated free thyroid hormone levels, and (d) elevated or inappropriately "normal" serum immunoreactive TSH concentrations. Because the pituitary gland is extremely sensitive to even minimal elevations of free T_4, a "normal" or elevated TSH level in any thyrotoxic patient indicates the inappropriate production of TSH.

TSH-Secreting Pituitary Adenomas

TSH-secreting pituitary tumors occur sporadically and release a biologically active hormone that is unresponsive to normal feedback control.[16] The mean age at diagnosis is around 40 years, with women being diagnosed more than men (8:7). These tumors may co-secrete prolactin or growth hormone; therefore, the patients may present with amenorrhea/galactorrhea or signs of acromegaly. Most patients present with classic symptoms and signs of thyrotoxicosis. Visual field defects may be present due to impingement of the optic chiasm by the tumor. Tumor growth and worsening visual field defects have been reported following antithyroid therapy because lowering of thyroid hormone levels is associated with loss of feedback inhibition from high thyroid hormone levels.

Diagnosis of a TSH-secreting adenoma should be made by demonstrating a lack of TSH response to TRH stimulation, inappropriate TSH levels, elevated α-subunit levels, and radiologic imaging; given the lack of routine availability of TRH, the other three criteria are essential. Note that some small tumors are not identified by MRI. Moreover, 10% of "normal" individuals may have incidental pituitary tumors or other benign focal lesions noted on pituitary imaging.

Transsphenoidal pituitary surgery is the treatment of choice for TSH-secreting adenomas. Pituitary gland irradiation is often given following surgery to prevent tumor recurrence. Dopamine agonists and octreotide have been used to treat tumors, especially those that co-secrete prolactin.

Pituitary Resistance to Thyroid Hormone

Resistance to thyroid hormone is a rare condition that can be due to a number of molecular defects, including mutations in the TRβ gene. Pituitary resistance to thyroid hormone (PRTH) refers to selective resistance of the pituitary thyrotrophs to thyroid hormone. As nonpituitary tissues respond normally to thyroid hormone, patients experience the toxic peripheral effects of thyroid hormone excess. About 90% of patients studied have an appropriate increase in TSH in response to TRH; conversely, the TSH will be suppressed by T_3 administration.

Patients with PRTH require treatment to reduce their elevated thyroid hormone levels. Determining the appropriate serum T_4 level is difficult because TSH cannot be used to evaluate the adequacy of therapy. Any reduction in thyroid hormone carries the risk of inducing thyrotroph hyperplasia. Ideally, agents that suppress TSH secretion could be used to treat these individuals. Glucocorticoids, dopaminergic drugs, somatostatin and its analogs, and thyroid hormone analogs with reduced metabolic activity have all been tried, but with relatively little benefit. β-Blocker therapy can also be used. Triiodothyroacetic acid (TRIAC), an agent that is devoid of thyromimetic properties on peripheral tissues, but blocks the secretion of TSH, has been used to treat this condition. However, it is not available in the United States. Given the ability of retinoid X receptor ligands to inhibit TSH production, drugs such as bexarotene may have therapeutic benefit in PRTH.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Thyrotoxicosis

General

- Signs and symptoms of thyrotoxicosis affect multiple organ systems. Patients often have symptoms for an extended period before the diagnosis of hyperthyroidism is made.

Symptoms

- The typical clinical manifestations of thyrotoxicosis include nervousness, anxiety, palpitations, emotional lability, easy fatigability, menstrual disturbances, and heat intolerance. A cardinal sign is weight loss despite an increased appetite.

- Elderly patients are more likely to develop atrial fibrillation with thyrotoxicosis than younger patients. The frequency of bowel movements may increase, but frank diarrhea is unusual. For the elderly patient and for the patient with severe disease, anorexia may be present as well. Palpitations are a prominent and distressing symptom, particularly in the patient with preexisting heart disease. Proximal muscle weakness is common and is noted on climbing stairs or in getting up from a sitting position. Women may note their menses are becoming scanty and irregular. Extremely thyrotoxic patients may have tachycardia, heart failure, psychosis, hyperpyrexia, and coma, a presentation described as thyroid storm.[8] Long-term hyperthyroidism may also be associated with a loss of bone mineral density and an increased risk of osteoporosis-related fracture.

Signs

- A variety of physical signs may be observed including warm, smooth, moist skin, exophthalmos (in Graves' disease only), pretibial myxedema (in Graves' disease only), and unusually fine hair. Separation of the end of the fingernails from the nail beds (onycholysis) may be noted. Ocular signs that result from thyrotoxicosis include retraction of the eyelids and lagging of the upper lid behind the globe when the patient looks downward (lid lag). Physical signs of a hyperdynamic circulatory state are common and include tachycardia at rest, a widened pulse pressure, and a systolic ejection murmur. Gynecomastia is sometimes noted in men. Neuromuscular examination often reveals a fine tremor of the protruded tongue and outstretched hands. Deep tendon reflexes are generally hyperactive. Thyromegaly is usually present. Elderly patients may present with the absence of clinical evidence of excess thyroid hormones (palpitations, anxiety, tremor, heat intolerance, and diaphoresis), but instead present with weight loss, apathy, and depression (apathetic hyperthyroidism).

Diagnosis

- Low TSH serum concentration. Elevated free and total T_4 and T_3 serum concentrations, particularly in more severe disease.

- Elevated radioactive iodine uptake (RAIU) by the thyroid gland when the hormone is being overproduced; suppressed RAIU in thyrotoxicosis due to thyroid inflammation (thyroiditis).

Other Tests

- Thyroid-stimulating antibodies (TSAbs)

- TG

- Thyrotropin receptor antibodies

TABLE 96-3

Differential Diagnosis of Thyrotoxicosis Based on Radioactive Iodine Uptake (RAIU)

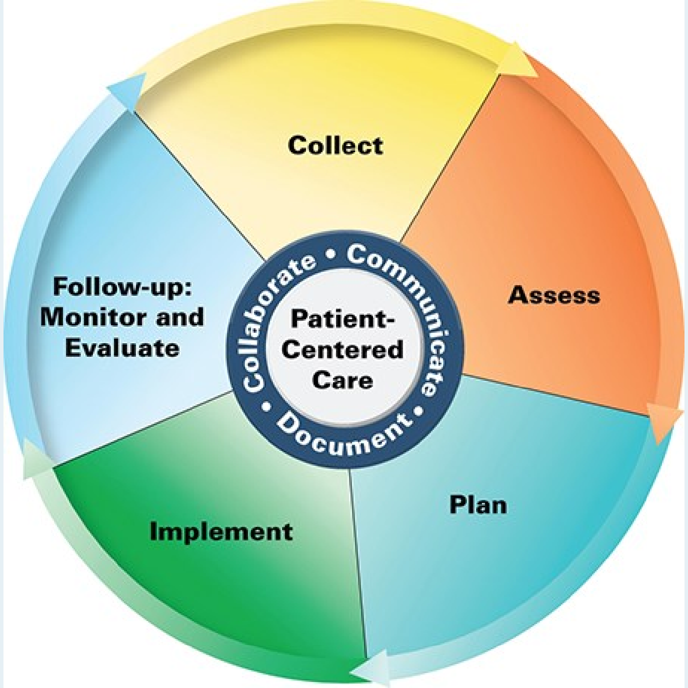
Increased RAIU[a]	Decreased RAIU
TSAb (Graves' disease)	Exogenous sources of thyroid hormone
Multinodular goiter	Medications containing thyroid hormone or iodine
Toxic adenoma	Painless thyroiditis
hCG (trophoblastic diseases)	Subacute thyroiditis
TSH-induced hyperthyroidism	Inflammatory thyroid disease
TSH-secreting tumors	Food sources containing thyroid gland
Selective pituitary resistance to T_4	Ectopic thyroid tissue
Thyroid stimulators other than TSH	Struma ovarii
	Metastatic follicular carcinoma

[a] The RAIU may be decreased if the patient has been recently exposed to excess iodine.

hCG, human chorionic gonadotropin; RAIU, radioactive iodine uptake; TSAb, thyroid-stimulating antibody.

PATIENT CARE PROCESS

Patient Care Process for the Management of Hyperthyroidism



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, sex, pregnancy status)
- Patient history (past medical, family, social) including patient signs and symptoms: warm, smooth, moist skin, palpitations, exophthalmos, pretibial myxedema, and unusually fine hair; anxiety, tremor, heat intolerance, tachycardia, weight loss, and menstrual disturbances (see Clinical Presentation Box)
- Current medications (including over-the-counter [OTC] and herbal medication use)
- Objective data
  - Heart rate, blood pressure (BP), weight, and body mass index (BMI)
  - Labs (eg, FT_4, TT_3, TSH, thyroid-stimulating antibodies; serum electrolytes, Scr, ALT)
  - Other diagnostic tests when indicated (eg, thyroid ultrasound, raidioactive iodine uptake [RAIU] scan)

Assess

- Cause of hyperthyroidism (see Table 96-3)
- Current medications that may contribute to or worsen hyperthyroidism
- Current medications that may interact with antithyroid therapy
- Appropriateness and effectiveness of current antithyroid regimen

Plan*

- Drug therapy regimen including specific antithyroid therapy, dose, and duration (see Table 96-5)
- Monitoring parameters including efficacy (eg, resolution of signs and symptoms) and safety (symptomatic hypothyroidism, adverse effects of medications), laboratory tests (TSH, FT_4, TT_3, LFTs, and CBC), and time frame
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

- Resolution of signs and symptoms
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Thyrotoxicosis

② Three common treatment modalities are used in the management of hyperthyroidism: surgery, antithyroid medications, and RAI (Table 96-5).

TABLE 96-5

Treatments for Hyperthyroidism Caused by Graves' Disease

Treatment	Advantages	Disadvantages	Comment
• Methimazole (first-line pharmacotherapy) • Propylthiouracil (second-line pharmacotherapy)	• Noninvasive • Low initial cost • Low risk of permanent hypothyroidism • Possible remissions due to immune effects	• Low cure rate (average 40%-50%) • Adverse drug reactions • Drug compliance	• First-line treatment in children, adolescents, and pregnancy • Initial treatment in severe cases or preoperative preparation
Radioactive iodine (^{131}I)	• Cure of hyperthyroidism • Lowest cost, before adjustment for quality of life	• Permanent hypothyroidism almost inevitable • Might worsen ophthalmopathy • Pregnancy must be deferred for 6-12 months; no breast-feeding • Small potential risk of exacerbation of hyperthyroidism	Best treatment for toxic nodules and toxic multinodular goiter
Surgery	Rapid, effective treatment, especially in patients with large goiters	• Most invasive • Least costly in long term after quality-of-life adjustment • Permanent hypothyroidism • Pain, scar	• Potential choice in pregnancy (2nd trimester) if major side effect from ATDs • Potential complications (recurrent laryngeal nerve damage, hypoparathyroidism) • Useful when coexisting suspicious nodule present • Option for patients who refuse radioiodine

Desired Outcomes

The overall therapeutic objectives are to eliminate the excess thyroid hormone and minimize the symptoms and long-term consequences of hyperthyroidism.

General Approach to Treatment

Therapy must be individualized based on the type and severity of hyperthyroidism, patient age and gender, the existence of nonthyroidal conditions, and response to previous therapy.[22,23] For example, patients with swallowing or breathing difficulties due to impingement of the esophagus or trachea are generally taken for surgical removal of the thyroid. Clinical guidelines for the treatment of hyperthyroidism have been published.[6] Selected recommendations from these guidelines are shown in Table 96-6.

TABLE 96-6

Selected Recommendations from the American Thyroid Association Hyperthyroidism Guidelines

Question	Recommendation Strength	Quality of Evidence
How should thyrotoxicosis be evaluated and initially managed?	β-Adrenergic blockade is recommended in all patients with symptomatic thyrotoxicosis, especially elderly patients and thyrotoxic patients with resting heart rates in excess of 90 beats per minute or coexistent cardiovascular disease.	Strong recommendation, moderate quality
If ^{131}I therapy is chosen (*for GD*), how should it be accomplished?	Sufficient radiation should be administered in a single dose (typically 10-15 mCi [370-555 MBq]) to render the patient with GD hypothyroid.	Strong recommendation, moderate quality
If ATDs are chosen as initial management of GD, how should the therapy be managed?	Methimazole should be used in virtually every patient who chooses antithyroid drug therapy for GD, except during the first trimester of pregnancy when propylthiouracil is preferred, in the treatment of thyroid storm, and in patients with minor reactions to methimazole who refuse radioactive iodine therapy or surgery.	Strong recommendation, moderate quality
If ATDs are chosen as initial management of GD, how should patients be monitored?	A differential WBC count should be obtained during febrile illness and at the onset of pharyngitis in all patients taking antithyroid medication.	Strong recommendation, low-quality
If thyroidectomy is chosen for treatment of GD, how should it be accomplished?	If surgery is chosen as the primary therapy for GD, near-total or total thyroidectomy is the procedure of choice.	Strong recommendation, low quality
If thyroidectomy is chosen for treatment of GD, how should it be accomplished?	Patients should be rendered euthyroid prior to the procedure.	Strong recommendation, moderate quality
How should overt hyperthyroidism	Patients should be treated with RAI therapy or thyroidectomy.	Weak recommendation, moderate quality

due to TMNG or TA be managed?		
How should GD be managed in children and adolescents?	Children with GD should be treated with MMI, RAI therapy, or thyroidectomy. RAI therapy should be avoided in very young children (<5 years). Under age 5, thyroidectomy should be performed.	Strong recommendation, moderate quality
How should hyperthyroidism in pregnancy be managed?	ATD therapy should be used for overt hyperthyroidism due to GD during pregnancy. PTU should be used when ATD therapy is given during the first trimester. MMI should be used when ATD therapy is started after the first trimester.	Strong recommendation, low quality
How should antithyroid treatment be managed during pregnancy?	GD during pregnancy should be treated with the lowest possible dose of ATDs needed to keep the mother's thyroid hormone levels at or slightly above the reference range for total T_4 and T_3 values in pregnancy (1.5 times above nonpregnant reference ranges in the second and third trimesters), and the TSH below the reference range for pregnancy. Similarly, free T_4 levels should be kept at or slightly above the upper limit of the pregnancy trimester reference range for the assay. Thyroid function should be assessed monthly, and the ATD dose adjusted as required.	Strong recommendation, low quality
How should other causes of thyrotoxicosis be managed?	Patients taking medications known to cause thyrotoxicosis, including interferon (IFN)-α, interleukin-2, tyrosine kinase inhibitors, and lithium, should be monitored clinically and biochemically at 6-month intervals for the development of thyroid dysfunction.	Strong recommendation, low quality

GD, Graves' disease; ^{131}I, radioactive I-131; TMNG, toxic multinodular goiter; TA, toxic adenoma; SH, subclinical hyperthyroidism.

Data from Reference [6].

Nonpharmacologic Therapy

Surgery should be considered for patients with a large thyroid gland (more than 80 g), severe ophthalmopathy, and a lack of remission on antithyroid drug treatment. In case of cosmetic issues or pressure symptoms, the choice in MNG stands between surgery, which is still the first choice, and radioiodine therapy if uptake is adequate. In addition to surgery, the solitary nodule, whether hot or cold, can be treated with percutaneous ethanol injection therapy. For hot nodules, radioiodine is the therapy of choice.[6] Appropriate preparation of the patient for thyroidectomy includes MMI until the patient is biochemically euthyroid (usually 6-8 weeks), followed by the addition of iodides (500 mg/day) for 10 to 14 days before surgery to decrease the vascularity of the gland. Propranolol for several weeks preoperatively and 7 to 10 days after surgery has also been used to maintain a pulse rate of less than 90 beats/min. Combined pretreatment with propranolol and 10 to 14 days of potassium iodide has also been advocated.

The overall complication rate when surgery is performed for MNG by an experienced endocrine surgeon is low. If subtotal thyroidectomy, or an operation that attempts to maintain euthyroidism, is performed for Graves' disease, there is a risk of recurrence of hyperthyroidism that is directly related to remnant thyroid gland size. Near-total thyroidectomy is generally recognized as the procedure of choice for patients with Graves' disease.[6] The complication rates of surgery for Graves' disease are low when surgery is performed by a high-volume thyroid surgeon. Surgical complications include hypoparathyroidism (up to 2%) and laryngeal nerve injury (up to 1%).

Pharmacologic Therapy

Antithyroid Medications

Thionamide Drugs

Two drugs within this category, MMI and PTU, are approved for the treatment of hyperthyroidism in the United States.[23] They are classified as thioureylenes (thionamides), which incorporate an N–C–S=N group into their ring structures.

Mechanism of Action

MMI and PTU share several mechanisms to inhibit the biosynthesis of thyroid hormone.[24] These drugs serve as preferential substrates for the iodinating intermediate of thyroid peroxidase and divert iodine away from potential iodination sites in TG. This prevents subsequent incorporation of iodine into iodotyrosines and ultimately iodothyronine ("organification"). Second, they inhibit the coupling of MIT and DIT to form T_4 and T_3. The coupling reaction may be more sensitive to these drugs than the iodination reaction. Experimentally, these drugs exhibit immunosuppressive effects, although the clinical relevance of this finding is unclear. For patients with Graves' disease, antithyroid drug treatment has been associated with lower TSAb titers and restoration of normal suppressor T-cell function. However, perchlorate (ClO_4^-), which has a different mechanism of action, also decreases TSAbs, suggesting that normalization of the thyroid hormone level may itself improve the abnormal immune function. PTU inhibits the peripheral conversion of T_4 to T_3. This effect is dose-related and occurs within hours of PTU administration. MMI does not have this effect. After several weeks of use, depletion of stored hormone and lack of continuing synthesis of thyroid hormone results in the clinical effects of these drugs.

Pharmacokinetics

Both ATDs are well absorbed (80%-95%) from the gastrointestinal tract, with peak serum concentrations about 1 hour after ingestion. The plasma half-life ranges of PTU and MMI are 1 to 2.5 and 6 to 9 hours, respectively, and are not appreciably affected by thyroid status. Urinary excretion is about 35% for PTU and less than 10% for MMI. These drugs are actively concentrated in the thyroid gland, which may account for the disparity between their relatively short plasma half-lives and the effectiveness of once-daily dosing regimens even with PTU. Approximately 60% to 80% of PTU is bound to plasma albumin, whereas MMI is not protein-bound. MMI readily crosses the placenta and appears in breast milk. Older studies suggested that PTU crosses the placental membranes only one-tenth as well as MMI; however, these studies were done in the course of therapeutic abortion early in pregnancy. Newer studies show little difference between fetal concentrations of PTU and MMI, and both are associated with elevated TSH in about 20% and low T_4 in about 7% of fetuses.

Dosing and Administration

MMI is available as 5 and 10 mg tablets and PTU as 50 mg tablets. MMI is approximately 10 to 20 times more potent than PTU. Initial therapy with MMI is given in two or three divided doses totaling 30 to 60 mg/day. PTU is given in dose ranges from 300 to 600 mg daily, usually in three or four divided doses. Although the traditional recommendation is for divided doses, evidence exists that both drugs can be given as single daily doses. Patients with severe hyperthyroidism may require larger initial doses, and some may respond better at these larger doses if the dose is divided. The maximal blocking doses of MMI and PTU are 120 and 1,200 mg daily, respectively. Once the intrathyroidal pool of thyroid hormone is reduced and new hormone synthesis is sufficiently blocked, clinical improvement should ensue. Usually, within 4 to 8 weeks of initiating therapy, symptoms will diminish and circulating thyroid hormone levels will return to normal. Now, the tapering regimen can be started. Changes in dose for each drug should be made monthly because the endogenously produced T_4 will reach a new steady-state concentration in this interval. Typical ranges of daily maintenance doses for MMI and PTU are 5 to 30 mg and 50 to 300 mg, respectively.

If the objective of therapy is to induce long-term remission in a patient with Graves' Disease, the patient should remain on continuous antithyroid drug therapy for a minimum of 12 to 24 months. Antithyroid drug therapy induces permanent remission rates of 10% to 98%, with an overall average of about 40% to 50%. This is much higher than the remission rate seen with propranolol alone (22%–36%). Patient characteristics for a favorable outcome include older patients (older than 40 years), low T_4:T_3 ratio (less than 20), a small goiter (less than 50 g), short duration of disease (less than 6 months), no previous history of relapse with ATDs, duration of therapy 1 to 2 years or longer, and low TSAb titers at baseline or a reduction with treatment.[24] A 2012 study provides preliminary evidence that a new assay that has better specificity for detection of antibodies that stimulate the TSH receptors, without detecting coexistent blocking antibodies, may be a useful predictor of remission of Graves' disease.[25]

A remission of Graves' hyperthyroidism most often occurs after 4 to 11 years of treatment, with a better prognosis if TSH binding inhibitor immunoglobulin (TBII) activity disappeared within 5 years without TBII fluctuation or enlargement of the goiter. A longer duration until normalization of TBII and higher final thyroid weight were associated with a poor prognosis.[26]

In another study in which patients were treated for their first episodes of Graves' hyperthyroidism, patients were treated for a minimum of 18 to 24 months of methimazole and then randomized to receive an additional 36 to 102 months of treatment or discontinued methimazole. Patients in both treatment groups were followed 48 months after discontinuing methimazole. Patients who received 60 to 120 months of methimazole were significantly more likely to achieve remission compared to patients who received only an 18- to 24-month course of treatment (85% vs 47%).[27]

A systematic review on remission rates in children with Graves' disease found that 23.7% of the participants achieved remission after 1.5 to 2.5 years of treatment and 75% achieved remission after 9 years of treatment. Adverse events occurred in 17.6% of patients but major side effects occurred in only 1.1%. In summary, longer treatment was associated with greater efficacy and is generally well tolerated.[28]

It is important that patients be followed every 6 to 12 months after remission occurs. If a relapse occurs, alternate therapy with RAI is preferred over a second course of ATDs, however, continued long-term low-dose MMI can be considered.[29] Relapses seem to plateau after about 5 years and eventually, 5% to 20% of patients will develop spontaneous hypothyroidism. Some researchers have speculated whether concurrent administration of T_4 with thionamide therapy for thyrotoxicosis and subclinical hyperthyroidism can reduce autoantibodies directed toward the thyroid gland and improve the remission rate. In general, this approach is not recommended because of the higher rates of side effects seen with the larger doses of ATDs needed for this regimen.[6]

Subclinical hyperthyroidism is defined as a serum TSH below the lower limit of the reference range combined with free T_4 and T_3 concentrations that are normal. Subclinical hyperthyroidism is associated with an increased risk of atrial fibrillation and may be associated with increased all-cause mortality. Some studies show an increased risk of hip fractures in postmenopausal women with subclinical hyperthyroidism. Most practitioners agree that the treatment of older patients (greater than 65 years) with TSH values below 0.1 mIU/L is reasonable. In patients who are younger or have TSH values of 0.1 to 0.4 mIU/L a decision whether to treat the patient for mild hyperthyroidism or to monitor thyroid function depends on the patient's cardiovascular risk factors and bone health.[6,30]

Adverse Effects

Minor adverse reactions to MMI and PTU have an overall incidence of 5% to 25% depending on the dose and the drug, whereas major adverse effects occur in 1.5% to 4.6% of patients receiving these drugs.[23] Pruritic maculopapular rashes (sometimes associated with vasculitis based on skin biopsy), arthralgias, and fevers occur in up to 5% of patients and may occur at a greater frequency with higher doses and in children. Rashes often disappear spontaneously but, if persistent, may be managed with antihistamines. Under the supervision of an allergist, desensitization to methimazole is an option for treating patients who experience rash or itching from the drug.[31]

One of the most common side effects is a benign transient leukopenia characterized by a WBC count of less than $4{,}000/\text{mm}^3$ ($4 \times 10^9/\text{L}$) This condition occurs in up to 12% of adults and 25% of children and sometimes can be confused with mild leukopenia seen in Graves' disease. This mild leukopenia is not a harbinger of the more serious adverse effect of agranulocytosis, so therapy can usually be continued. If a minor adverse reaction occurs with one ATD, the alternate thiourea may be tried, but cross-sensitivity occurs for about 50% of patients.[23]

Agranulocytosis is one of the serious adverse effects of thiourea drug therapy and is characterized by fever, malaise, gingivitis, oropharyngeal infection, and a granulocyte count less than $250/\text{mm}^3$ ($0.250 \times 10^9/\text{L}$).[23] These drugs are concentrated in granulocytes, and this reaction may represent a direct toxic effect rather than hypersensitivity. This toxic reaction has occurred with both thioureas, and the incidence varies from 0.5% to 6%. It is higher for patients over age 40 receiving an MMI dose greater than 40 mg/day or the equivalent dose of PTU, and is more frequent with initial MMI doses of 30 mg compared with 15 mg. A systematic review and meta-analysis found strong associations of ATD-induced agranulocytosis with HLAB* 27:05, HLA-B*38:02, and HLA-DRB1*08:03 alleles, especially in carbimazole/methimazole-induced agranulocytosis.[32]

Agranulocytosis usually develops in the first 3 months of therapy. Because the onset is sudden, routine WBC count monitoring has not been recommended. Colony-stimulating factors have been used with some success to restore cell counts to normal, but it is unclear how effective this form of therapy is compared with routine supportive care. Peripheral lymphocytes obtained from patients with PTU-induced agranulocytosis undergo a transformation in the presence of other thionamides, suggesting that these severe reactions are immunologically mediated and patients should not receive other thionamides. Aplastic anemia has been reported with MMI and may be associated with an inhibitor to colony-forming units. Once ATDs are discontinued, clinical improvement is seen over several days to weeks. Patients should be counseled to discontinue therapy and contact their physician when flu-like symptoms such as fever, malaise, or a sore throat develops. Treatment of agranulocytosis requires immediate suspension of the ATD and initiation of broad-spectrum antibiotics. Definitive treatment of hyperthyroidism is subsequently required.[33] Clinicians will often concomitantly provide an order for a complete blood cell count (with WBC count differential) when prescribing MMI or PTU therapy. If the patient becomes ill and is unable to reach the provider, the patient can still visit the nearest laboratory to have potential agranulocytosis diagnosed.

Arthralgias and a lupus-like syndrome (sometimes in the absence of antinuclear antibodies) have been reported in 4% to 5% of patients. This generally occurs after 6 months of therapy. Uncommonly, polymyositis, presenting as proximal muscle weakness and elevated creatine phosphokinase, has been reported with PTU administration. Gastrointestinal intolerance is also reported to occur in 4% to 5% of patients. Hypoprothrombinemia is a rare complication of thionamide therapy. Patients who have experienced a major adverse reaction to one thiourea drug should not be converted to the alternate drug because of cross-sensitivity.[6]

In 2019 the European Medicines Agency (EMA) issued a warning and the product labeling for methimazole was changed to include acute pancreatitis as a serious side effect. This decision was based on six case reports of acute pancreatitis in patients treated with methimazole, developing within 90 days of starting the drug. In one study, ongoing use of methimazole was associated with a 56% increase in the risk of being admitted to the hospital for acute pancreatitis, whereas propylthiouracil was not associated with an increased risk.[34]

Hepatotoxicity can be seen with both MMI and PTU, with a prevalence of approximately 1.3%. At moderate doses, some authors have found that initial hepatic enzyme elevations eventually normalize in most patients with continued therapy. PTU-induced subclinical liver injury is common and is usually transient and asymptomatic. Thus, it has generally been thought that therapy with PTU may be continued with caution in the absence of symptoms and hyperbilirubinemia. However, a 1997 literature review documented 49 cases of hepatotoxicity. Twenty-eight cases were associated with PTU use, and 21 cases were associated with MMI use. The hepatotoxicity was associated with seven deaths and three deaths in the PTU and MMI groups, respectively. There did not appear to be a relationship between the dose or duration of thionamide treatment and outcome. During the past 20 years of PTU use in the United States, 22 adults developed severe hepatotoxicity leading to nine deaths and five liver transplants. The risk of this complication was greater in children (1:2,000) than in adults (1:10,000). A recent reanalysis of data reported to the Food and Drug Administration (FDA) from 1982 to 2008 found that toxicity in children was generally related to higher doses of PTU and that toxicity in both children and adults was associated with therapy lasting more than 4 months in duration.[35] Thus, the American Thyroid Association (ATA) and the FDA recommend against the use of PTU as first-line therapy in either adults or children.[6] One of three exceptions includes the first trimester of pregnancy, when the risk of MMI-induced embryopathy may exceed that of PTU-induced hepatotoxicity. Other exceptions include intolerance to MMI and thyroid storm.

Older reports suggested that congenital skin defects (ie, aplasia cutis) may be caused by MMI and carbimazole, although a registry review from the Netherlands could not find an association between maternal use of these drugs and skin defects. Several serious congenital malformations including tracheoesophageal fistulas and choanal atresia have been observed with MMI and carbimazole but not PTU use during pregnancy. PTU has traditionally been considered the drug of choice throughout pregnancy for women with hyperthyroidism, because of concerns about the possible teratogenic effects of MMI. However, currently heightened concerns about the greater risk of hepatotoxicity with PTU when compared to MMI have led to the recommendation that PTU no longer be considered a first-line drug, except during the first trimester of pregnancy. The choice of antithyroid agent during pregnancy has been further complicated by two studies that suggest that fetuses exposed to either MMI or PTU during gestation may increase the risk of drug-induced fetal malformations. A Danish study revealed that 2% to 3% of children exposed to PTU developed birth defects associated with this therapy.[36] In another study, PTU- associated birth defects, though less severe than MMI-associated birth defects, occurred with similar incidence in a Korean population.[37] Recommendations regarding the management of thyroid disease during pregnancy recommends using the lowest effective dose of the ATD as possible, targeting maternal serum FT_4/TT_4 at the upper limit or moderately above the reference range and utilizing a team approach with close collaboration among endocrinologists, maternal-fetal medicine specialists, and neonatologists.[38]

While there is debate regarding optimal therapy of Graves' disease, a study assessing the quality of life (QoL) in patients 6 to 10 years after treatment for Graves' disease with RAI, thyroidectomy, or ATDs. Patients treated with RAI had worse thyroid-related and general QoL than patients treated with ATD or thyroidectomy on the majority of QoL scales. However, regardless of treatment modality, patients with GD had worse thyroid-related QoL 6 to 10 years after diagnosis compared to the general population.[39]

Iodides

Iodide was the first form of drug therapy for Graves' disease. Its mechanism of action is to acutely block thyroid hormone release, inhibit thyroid hormone biosynthesis by interfering with intrathyroidal iodide utilization (the Wolff–Chaikoff effect), and decrease the size and vascularity of the gland. This early inhibitory effect provides symptom improvement within 2 to 7 days of initiating therapy, and serum T_4 and T_3 concentrations may be reduced for a few weeks. Despite the reduced release of T_4 and T_3, thyroid hormone synthesis continues at an accelerated rate, resulting in a gland rich in stored hormones. The normal and hyperfunctioning thyroid soon escapes from this inhibitory effect within 1 to 2 weeks by decreasing the active transfer of iodide into the gland. Iodides are often used as adjunctive therapy to prepare a patient with Graves' disease for surgery, to acutely inhibit thyroid hormone release and quickly attain the euthyroid state in severely thyrotoxic patients with cardiac decompensation, or to inhibit thyroid hormone release following RAI therapy. However, large doses of iodine may exacerbate hyperthyroidism or indeed precipitate hyperthyroidism in some previously euthyroid individuals (Jod–Basedow disease). This Jod–Basedow phenomenon is most common in iodine-deficient areas, particularly for patients with pre-existing nontoxic goiter. Iodide is contraindicated in toxic MNG as the autonomous tissue utilizes the iodine for subsequent thyroid hormone synthesis. Although it is not the standard of care in the United States, potassium iodide therapy was effective in two-thirds of cases, and induced remission in approximately 40% of the patients in a Japanese study of hyperthyroid patients with thionamide-associated side effects.[40] Because iodide crosses the placenta and may cause hypothyroidism and goiter in the newborn, its use is generally avoided in pregnant women.

Potassium iodide is available either as a saturated solution (SSKI), which contains 38 mg of iodide per drop or as Lugol's solution, which contains 6.3 mg of iodide per drop. The typical starting dose of SSKI is 3 to 10 drops daily (120-400 mg) in water or juice. There is no documented advantage to using doses in excess of 6 to 8 mg/day. When used to prepare a patient for surgery, it should be administered 7 to 14 days preoperatively. As an adjunct to RAI, SSKI should not be used before, but rather 3 to 7 days after RAI treatment, so that the radioactive iodide can concentrate in the thyroid. The most frequent toxic effects with iodide therapy are hypersensitivity reactions (skin rashes, drug fever, rhinitis, and conjunctivitis), salivary gland swelling, "iodism" (metallic taste, burning mouth and throat, sore teeth and gums, symptoms of a head cold, and sometimes stomach upset and diarrhea), and gynecomastia.

Other compounds containing organic iodide have also been used therapeutically for hyperthyroidism. These include various radiologic contrast media that share a triiodoaminobenzene and monoaminobenzene ring with a propionic acid chain (eg, iopanoic acid and sodium ipodate). The effect of these compounds is a result of the iodine content inhibiting thyroid hormone release as well as competitive inhibition of 5'- monodeiodinase conversion related to their structures, which resemble thyroid analogs. Unfortunately, these extremely useful agents are no longer available in the United States.

Adrenergic Blockers

Because many of the manifestations of hyperthyroidism are mediated by β -adrenergic receptors, β-blockers (especially propranolol) have been used widely to ameliorate symptoms such as palpitations, anxiety, tremor, and heat intolerance. Although β-blockers are quite effective for symptom control, they have no effect on the urinary excretion of calcium, phosphorus, hydroxyproline, creatinine, or various amino acids, suggesting a lack of effect on peripheral thyrotoxicosis and protein metabolism. Furthermore, β-blockers neither reduce TSAb nor prevent thyroid storm. Propranolol and nadolol partially block the conversion of T_4 to T_3, but this contribution to the overall therapeutic effect is small in magnitude. Inhibition of conversion of T_4 to T_3 is mediated by D-propranolol, which is devoid of β-blocking activity, and L-propranolol, which is responsible for the antiadrenergic effects, has little effect on the conversion.

β-Blockers are usually used as adjunctive therapy with ATDs, RAI, or iodides when treating Graves' disease or toxic nodules; in preparation for surgery; or in thyroid storm. The only conditions for which β-blockers are primary therapy for thyrotoxicosis are those associated with thyroiditis. The dose of propranolol required to relieve adrenergic symptoms is variable, but an initial dose of 20 to 40 mg four times daily is effective (goal heart rate less than 90 beats/min) for most patients. Younger or more severely toxic patients may require as much as 240 to 480 mg/day because there seems to be an increased clearance rate for these patients. β-Blockers are contraindicated for patients with decompensated heart failure unless it is caused solely by tachycardia (high output failure). Nonselective agents and those lacking intrinsic sympathomimetic activity should be used with caution for patients with asthma and bronchospastic chronic obstructive lung disease. β-Blockers that are cardioselective and have intrinsic sympathomimetic activity may have a slight margin of safety in these situations. Other patients in whom contraindications exist are those with sinus bradycardia, those receiving monoamine oxidase inhibitors or tricyclic antidepressants, and those with spontaneous hypoglycemia. β-Blockers may also prolong gestation and labor during pregnancy. Other side effects include nausea, vomiting, anxiety, insomnia, light-headedness, bradycardia, and hematologic disturbances.

Antiadrenergic agents such as centrally acting sympatholytics and calcium channel antagonists may have some role in the symptomatic treatment of hyperthyroidism. These drugs might be useful when contraindications to β-blockade exist. When compared with nadolol 40 mg twice daily, clonidine 150 mcg twice daily reduced plasma catecholamines, whereas nadolol increased both epinephrine and norepinephrine after 1 week of treatment. Diltiazem 120 mg given every 8 hours reduced heart rate by 17%; fewer ventricular extrasystoles were noted after 10 days of therapy, and diltiazem has been shown to be comparable to propranolol in lowering heart rate and BP.

Therapeutic plasmapheresis is an effective alternative treatment option to prepare for ablative treatment in patients that have side effects or who do not respond adequately to anti-thyroid drugs.[41] In a retrospective study in patients with Graves' disease, amiodarone-induced thyrotoxicosis, or toxic nodular goiter, the median free triiodothyronine (FT_3) fell from 9.9 pg/mL to 4.0 pg/mL (0.15 pmol/L to 0.06 pmol/L) and FT_4 levels fell from 2.9 ng/dL to 1.6 ng/dL (37.3 pmol/L to 20.6 pmol/L). Each apheresis session lasted for 2.5 to 3 hours and was performed daily until normal thyroid function was achieved (median 4, range 1-7 days).

Radioactive Iodine

Although other radioisotopes have been used to ablate thyroid tissue, ^{131}I is considered to be the agent of choice for Graves' disease, toxic autonomous nodules, and toxic MNGs.[6] RAI is administered as a colorless and tasteless liquid that is well absorbed and concentrates in the thyroid. ^{131}I is a β- and γ-emitter with a tissue penetration of 2 mm and a half-life of 8 days. Other organs take up ^{131}I, but the thyroid gland is the only organ in which organification of the absorbed iodine takes place. Initially, RAI disrupts hormone synthesis by incorporating into thyroid hormones and TG. Over a period of weeks, follicles that have taken up RAI and surrounding follicles develop evidence of cellular necrosis, breakdown of follicles, development of bizarre cell forms, nuclear pyknosis, and destruction of small vessels within the gland, leading to edema and fibrosis of the interstitial tissue. Pregnancy is an absolute contraindication to the use of RAI since radiation will be delivered to the fetal tissue, including the fetal thyroid.

β-Blockers may be given any time without compromising RAI therapy, accounting for their role as a mainstay of adjunctive therapy to RAI treatment. If iodides are administered, they should be given 3 to 7 days after RAI to prevent interference with the uptake of RAI in the thyroid gland. Because thyroid hormone levels will transiently increase following RAI treatment due to the release of preformed thyroid hormone, patients with cardiac disease and elderly patients are often treated with thionamides prior to RAI ablation. For patients with underlying cardiac disease, it may be necessary to reinstitute antithyroid drug therapy following RAI ablation. The standard practice is to withdraw the thionamide 4 to 6 days prior to RAI treatment and to reinstitute it 4 days after therapy is concluded. Administering antithyroid drug therapy immediately following RAI treatment may result in a higher rate of posttreatment recurrence or persistent hyperthyroidism. Pretreatment with PTU may lead to higher rates of treatment failure, but this does not appear to be the case with MMI pretreatment. The use of lithium, as adjunctive therapy to RAI therapy, has multiple benefits of increasing the cure rate, shortening the time to cure, and preventing a post-therapy increase in thyroid hormone levels.[42] Lithium is likely to achieve these effects by increasing RAI retention in the thyroid and inhibiting thyroid hormone release from the gland, although it is not commonly used due to its narrow therapeutic index.

Corticosteroid administration will blunt and delay the rise in antibodies to the TSH receptor, TG, and thyroid peroxidase while reducing T_3 and T_4 concentrations following RAI. Theoretically, if a shared thyroidal and orbital antigen is involved in the pathogenesis of Graves' ophthalmopathy, antigen released with RAI treatment could aggravate pre-existing eye disease. There is some disagreement as to what degree of ophthalmopathy should be considered a contraindication to RAI. However, in those with moderate or severe orbitopathy, it seems reasonable to delay RAI until the patient's eye disease has been stable. Traditionally, corticosteroids, radiation therapy, and surgical correction have been the mainstays of therapy for Graves' ophthalmopathy. Rituximab, tocilizumab, and teprotumumabIn have been assessed in RCTs.[43] In 2020, the FDA approved teprotumumab, a monoclonal anti-insulin-like growth factor I receptor antibody for the treatment of thyroid eye disease. Patients completing the eight-infusion treatment course of teprotumumab over 24 weeks demonstrated significant improvement in proptosis, diplopia, quality of life, and Clinical Activity Score.[44] The most commonly reported adverse events with teprotumumab were muscle spasm (18%), hearing loss (10%), and hyperglycemia (8%).

Destruction of the gland attenuates the hyperthyroid state, and hypothyroidism commonly occurs months to years following RAI.[6,24] The goal of therapy is to destroy overactive thyroid cells, and a single dose of 4,000 to 8,000 rad (40 to 80 Gy) results in a euthyroid state in 60% of patients at 6 months or less. The remaining 40% become euthyroid within 1 year, requiring two or more doses. It is advisable that a second dose of RAI be given 6 months after the first RAI treatment if the patient remains hyperthyroid.[6] Variables that predict an unsuccessful outcome of RAI include gender (men are less likely to develop hypothyroidism), race, the size of the thyroid (euthyroidism is less likely in large glands), the severity of disease, and perhaps a higher level of TSAb. Predictors of successful treatment with RAI included higher ablative dose, female gender, lower free T_4 levels at diagnosis, and absence of a palpable goiter.[24] The acute, short-term side effects of ^{131}I therapy are minimal and include mild thyroidal tenderness and dysphagia. Concern about mutations and congenital defects now appears to be unfounded because long-term follow-up studies have not revealed an increased risk for these complications.[45] Although RAI is very effective in the treatment of hyperthyroidism, long-term follow-up from Great Britain suggests that among patients with hyperthyroidism treated with RAI, mortality from all causes and mortality resulting from cardiovascular and cerebrovascular disease and fracture are increased.

A common approach to Graves' hyperthyroidism is to administer a single dose of 5 to 15 mCi (185 to 555 mBq; 80-200 µCi/g of tissue [3.0 to 7.4 mBq/g]). The optimal method for determining ^{131}I treatment doses for Graves' hyperthyroidism is unknown, and techniques have varied from a fixed dose to more elaborate calculations based on gland size, iodine uptake, and iodine turnover.[6] In a trial of 88 patients with Graves' disease, no difference in outcome was seen among high or low, fixed or adjusted doses. Thyroid glands estimated to weigh more than 80 g may require larger doses of RAI. Larger doses are likely to induce hypothyroidism and are seldom given outside the United States due to the imposition of stringent safety restrictions. For example, in the United Kingdom, a nursery school teacher is advised to stay out of school for 3 weeks following a 15 mCi (555 mBq) dose of ^{131}I.

Special Populations

Graves' Disease and Pregnancy

Inappropriate increase in the production of hCG is a cause of abnormal thyroid function tests during the first half of pregnancy, and hCG can cause either subclinical (normal T_4 and suppressed TSH) or overt hyperthyroidism. This is because the homology of hCG and TSH leads to hCG-mediated stimulation through the TSH receptor. At hCG concentrations greater than 400 IU/mL (kIU/L), TSH levels were invariably suppressed and free T_4 levels were generally above the normal range. Most patients with hCG greater than 200 IU/mL (kIU/L) did not have symptoms of hyperthyroidism. The variability of the thyrotropic potency of hCG is believed to depend on its carbohydrate composition.

A very comprehensive guideline has been published by the ATA regarding the management of thyroid disease during pregnancy.[38] Hyperthyroidism during pregnancy is almost solely caused by Graves' disease, with approximately 0.1% to 0.4% of pregnancies affected. Although the increased metabolic rate is usually well tolerated in pregnant women, two symptoms suggestive of hyperthyroidism during pregnancy are failure to gain weight despite a good appetite and persistent tachycardia. There is no increase in maternal mortality or morbidity in well-controlled patients. However, postpartum thyroid storm has been reported in about 20% of untreated individuals. Fetal loss is also more common, due to the fact that spontaneous abortion and premature delivery are more common in untreated pregnant women, as are low-birth-weight infants and eclampsia. Transplacental passage of TSAb may occur, causing fetal as well as neonatal hyperthyroidism. An uncommon cause of hyperthyroidism is molar pregnancy; women present with a large-for-dates uterus and evacuation of the uterus is the preferred management approach.

Because RAI is contraindicated in pregnancy and surgery is usually not recommended (especially during the first trimester), antithyroid drug therapy is usually the treatment of choice for hyperthyroidism. MMI readily crosses the placenta and appears in breast milk.

As previously mentioned, propylthiouracil has been considered the drug of choice during the first trimester of pregnancy, with the lowest possible doses used to maintain the maternal T_4 level in the high-normal range.[38] During this period the risk of MMI-associated embryopathy is believed to outweigh that of PTU-associated hepatotoxicity. To prevent fetal goiter and suppression of fetal thyroid function, PTU is usually prescribed in daily doses of 300 mg or less and tapered to 50 to 150 mg daily after 4 to 6 weeks. PTU doses of less than 200 mg daily are unlikely to produce fetal goiter. During the second and third trimesters, when the critical period of organogenesis is complete, MMI has been thought to be the drug of choice because of the greater risk of hepatotoxicity with PTU.[38] However, it is unclear whether this strategy of switching thionamides, and thus exposing the fetus to both drugs, is the optimum approach.[36] Thionamide doses should be adjusted to maintain free T_4 within 10% of the upper normal limit of the nonpregnant reference range. During the last trimester, TSAbs fall spontaneously, and some patients will go into remission so that ATD doses may be reduced. A rebound in maternal hyperthyroidism occurs in about 10% of women postpartum and may require more intensive treatment than in the last trimester of pregnancy.

Neonatal and Pediatric Hyperthyroidism

Following delivery, some babies of hyperthyroid mothers will be hyperthyroid due to placental transfer of TSAbs, which stimulates thyroid hormone production in utero and postpartum. This is likely if the maternal TSAb titers were quite high. The disease is usually expressed 7 to 10 days postpartum and treatment with ATDs (PTU 5-10 mg/kg/day or MMI 0.5-1 mg/kg/day) may be needed for as long as 8 to 12 weeks until the antibody is cleared (immunoglobulin G half-life is about 2 weeks). Iodide (potassium iodide one drop per day or Lugol's solution one to three drops per day) and sodium ipodate may be used for the first few days to acutely inhibit hormone release.

Childhood hyperthyroidism has classically been managed with either MMI or PTU. Long-term follow-up studies suggest that this form of therapy is quite acceptable, with 25% of a cohort experiencing remission every 2 years. Again, current recommendations suggest using MMI as a first-line agent in both adults and children.[6]

Thyroid Storm

Thyroid storm is a life-threatening medical emergency characterized by decompensated thyrotoxicosis, high fever (often more than 39.4°C [103°F]), tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea.[8] Graves' disease and less commonly toxic nodular goiter are usually the underlying thyrotoxic pathology.

Precipitating factors for thyroid storm include infection, trauma, surgery, RAI treatment, and withdrawal from ATDs. Although the duration of clinical decompensation lasts for an average duration of 72 hours, symptoms may persist up to 8 days. With aggressive treatment, the mortality rate has been lowered to 20%. The following therapeutic measures should be instituted promptly: (a) suppression of thyroid hormone formation and secretion, (b) antiadrenergic therapy, (c) administration of corticosteroids, and (d) treatment of associated complications or coexisting factors that may have precipitated the storm. Specific agents used in thyroid storm are outlined in Table 96-7. PTU in large doses may be the preferred thionamide because, in addition to interfering with the production of thyroid hormones, it also blocks the peripheral conversion of T_4 to T_3. However, β-blockers and corticosteroids will serve the same purpose. A theoretical advantage of MMI is that it has a longer duration of action. If patients are unable to take medications orally, the tablets can be crushed into suspension and instilled by a gastric or rectal tube. Iodides, which rapidly block the release of preformed thyroid hormone, should be administered after thionamide is initiated to inhibit iodide utilization by the overactive gland. If iodide is administered first, it could theoretically provide a substrate to produce even higher levels of thyroid hormone.

TABLE 96-7

Drug Dosages Used in the Management of Thyroid Storm

Drug	Regimen
Propylthiouracil	900-1,200 mg/day orally in four or six divided doses
Methimazole	90-120 mg/day orally in four or six divided doses
Sodium iodide	Up to 2 g/day IV in single or divided doses
Lugol’s solution	5-10 drops three times a day in water or juice
Saturated solution of potassium iodide (SSKI)	1-2 drops three times a day in water or juice
Propranolol	40-80 mg every 6 hours
Dexamethasone	5-20 mg/day orally or IV in divided doses
Prednisone	25-100 mg/day orally in divided doses
Methylprednisolone	20-80 mg/day IV in divided doses
Hydrocortisone	100-400 mg/day IV in divided doses

Antiadrenergic therapy with the short-acting agent esmolol is preferred, both because it may be used in the patient with pulmonary disease or at risk for cardiac failure and because its effects may be rapidly reversed. Corticosteroids are generally recommended, although there is no convincing evidence of adrenocortical insufficiency in thyroid storm, and the benefits derived from steroids may be caused by their antipyretic action and their effect of stabilizing BP.[8] General supportive measures, including acetaminophen as an antipyretic (do not use aspirin or other NSAIDs because they may displace bound thyroid hormone), fluid and electrolyte replacement, sedatives, digitalis, antiarrhythmics, insulin, and antibiotics, should be given as indicated. Plasmapheresis and peritoneal dialysis have been used to remove excess hormone (and to remove thyroid-stimulating immunoglobulins in Graves’ disease) when the patient has not responded to more conservative measures, although these measures do not always work.

EVALUATION OF THERAPEUTIC OUTCOMES—THYROTOXICOSIS

After therapy (surgery, thionamides, or RAI) for hyperthyroidism has been initiated, patients should be evaluated on a monthly basis until they reach a euthyroid condition. Clinical signs of continuing thyrotoxicosis (tachycardia, weight loss, and heat intolerance, among others) or the development of hypothyroidism (bradycardia, weight gain, and lethargy, among others) should be noted. β-Blockers may be used to control symptoms of thyrotoxicosis until the definitive treatment has returned the patient to a euthyroid state. If T_4 replacement is initiated, the goal is to maintain both the free T_4 level and the TSH concentration in the normal range. Once a stable dose of T_4 is identified, the patient may be followed up every 6 to 12 months.

A common, potentially confusing clinical situation should be mentioned. Some patients may have TSH concentrations that continue to be suppressed despite having free T_4 concentrations that become normal or low. For patients with long-standing hyperthyroidism, the pituitary thyrotrophs are responsible for making TSH become atrophic. The average amount of time required for these cells to resume normal functioning is 6 to 8 weeks. Therefore, if a thyrotoxic patient has his or her free T_4 concentration lowered rapidly before the thyrotrophs resume normal function, a period of “transient central hypothyroidism” will be observed. In addition, autoimmune mechanisms may also play a role, with a slower TSH recovery in patients with higher titers of thyroid-binding inhibitory immunoglobulins.

CONCLUSION—HYPERTHYROIDISM

Management of hyperthyroidism includes treatment with ATDs, RAI, or thyroidectomy. Optimal treatment is patient-specific, depending on patient clinical presentation, including age, history of arrhythmias or atherosclerotic disease, goiter size, and severity of thyrotoxicosis. ATDs are the primary therapy during pregnancy.

HYPOTHYROIDISM

Hypothyroidism is defined as the clinical and biochemical syndrome resulting from decreased thyroid hormone production.[46] Biochemically, primary hypothyroidism is defined as TSH concentrations above the reference range and FT_4 and/or triiodothyronine levels below the reference range.

EPIDEMIOLOGY—HYPOTHYROIDISM

Overt hypothyroidism occurs in 1.5% to 2% of women and 0.2% of men, and its incidence increases with age. In the Third National Health and Nutrition Examination Survey (NHANES III), levels of serum TSH and total T_4 were measured in a representative sample of adolescents and adults (age 12 or older). Among 16,533 people who neither were taking thyroid medication nor reported histories of thyroid disease, 3.9% had subclinical hypothyroidism (serum TSH more than 4.5 mIU/L, and T_4 normal), and 0.2% had "clinically significant" hypothyroidism (TSH more than 4.5 mIU/L, and T_4 less than 4.5 mcg/dL [58 nmol/L]).[7] Subclinical hypothyroidism is commonly regarded as a sign of impending thyroid failure.

ETIOLOGY AND PATHOPHYSIOLOGY —HYPOTHYROIDISM

The vast majority of patients have primary hypothyroidism due to thyroid gland failure caused by chronic autoimmune thyroiditis. Special populations with higher risk of developing hypothyroidism include postpartum women, individuals with a family history of autoimmune thyroid disorders and patients with previous head and neck or thyroid irradiation or surgery, other autoimmune endocrine conditions (eg, type 1 diabetes mellitus, adrenal insufficiency, and ovarian failure), some other nonendocrine autoimmune disorders (eg, celiac disease, vitiligo, pernicious anemia, Sjögren's syndrome, and multiple sclerosis), primary pulmonary hypertension, and Down's and Turner's syndromes.

Central hypothyroidism is rare and affects both sexes equally. It is more often associated with pituitary than hypothalamic disorders but frequently involves both.[47] Biochemically, central hypothyroidism is defined by low or low-to-normal TSH concentrations and a disproportionately low concentration of FT_4. Secondary hypothyroidism due to pituitary failure is uncommon but should be suspected in a patient with decreased levels of T_4 and inappropriately normal or low TSH levels. Most patients with secondary hypothyroidism due to inadequate TSH production will have clinical signs of more generalized pituitary insufficiency, such as abnormal menses and decreased libido, or evidence of a pituitary adenoma, such as visual field defects, galactorrhea, or acromegaloid features, but isolated TSH deficiency can be congenital or acquired as a result of autoimmune hypophysitis.[48] Generalized (peripheral and central) resistance to thyroid hormone is extremely rare.

Table 96-8 outlines the causes of hypothyroidism. These causes fall into two broad categories involving dysfunction of the thyroid gland (primary hypothyroidism) or dysfunction of the pituitary or hypothalamus (secondary hypothyroidism).

TABLE 96-8

Causes of Hypothyroidism

- **Primary hypothyroidism**
- Hashimoto's disease
- Iatrogenic hypothyroidism
- Less common:
    - Iodine deficiency
    - Enzyme defects
    - Thyroid hypoplasia
    - Goitrogens

- **Secondary hypothyroidism**
- Pituitary disease
- Hypothalamic disease

Chronic Autoimmune Thyroiditis

⑦ Autoimmune thyroiditis (Hashimoto's disease) is the most common cause of spontaneous hypothyroidism in the adult.[46] Patients may present either with goitrous thyroid gland enlargement and mild hypothyroidism or with thyroid gland atrophy and more severe thyroid hormone deficiency. Both forms of autoimmune thyroiditis probably result from cell- and antibody-mediated thyroid injury. The presence of specific defects in suppressor T-lymphocyte function leads to the survival of a randomly mutating clone of helper T lymphocytes, which are directed against normally occurring antigens on the thyroid membrane. Once these T lymphocytes interact with thyroid membrane antigen, B lymphocytes are stimulated to produce thyroid antibodies. Readers are referred to an excellent review regarding biochemical testing in thyroid disorders.[49] Antithyroid peroxidase (antimicrosomal) antibodies are present in virtually all patients with Hashimoto's thyroiditis and appear to be directed against the enzyme thyroid peroxidase. These antibodies are capable of fixing complement and inducing cytotoxic changes in thyroid cells. Antibodies that are capable of stimulating thyroid growth through interaction with the TSH receptor may occasionally be found particularly in goitrous hypothyroidism; conversely, antibodies that inhibit the trophic effects of TSH may be present in the atrophic type.

Iatrogenic Hypothyroidism

Iatrogenic hypothyroidism follows exposure to destructive amounts of radiation (radioiodine or external radiation) or surgery. Hypothyroidism occurs within 3 months to a year after ^{131}I therapy in most patients treated for Graves' disease. Thereafter, it occurs at a rate of approximately 2.5% each year. External radiation therapy to the region of the thyroid using doses of greater than 2,500 centigray (cGy) for therapy of neck carcinoma also causes hypothyroidism. This effect is dose-dependent and more than 50% of patients who receive more than 4,000 cGy to the thyroid bed develop hypothyroidism. Total thyroidectomy causes hypothyroidism within 1 month. Excessive doses of thionamides used to treat hyperthyroidism can also cause iatrogenic hypothyroidism.

Other Causes of Primary Hypothyroidism

Iodine deficiency, enzymatic defects within the thyroid gland, thyroid hypoplasia, and maternal ingestion of goitrogens during fetal development may cause cretinism. Early recognition and treatment of the resultant thyroid hormone deficiency is essential for optimal mental development. Large-scale neonatal screening programs in North America, Europe, Japan, and Australia are now in place. The frequency of congenital hypothyroidism in North America and Europe is 1 per 3,500 to 4,000 live births. In the United States, there are racial differences in the incidence of congenital hypothyroidism, with White patients being affected seven times as frequently as Black patients.

In the adult, hypothyroidism is rarely caused by iodine deficiency and goitrogens. Iodine ingestion in the form of expectorants can lead to hypothyroidism. In sensitive persons (particularly those with autoimmune thyroiditis), the iodide blocks the synthesis of thyroid hormone, leading to increased secretion of TSH and thyroid enlargement. Thus, both iodine excess and iodine deficiency can cause decreased secretion of thyroid hormone. An example of a goitrogen that can induce hypothyroidism is raw bok choy. Several medications can cause hypothyroidism, including lithium, amiodarone, interferon-α, interleukin-2, tyrosine kinase inhibitors, perchlorate, and checkpoint inhibitors.[50]

Pituitary Disease

TSH is required for normal thyroid secretion. Thyroid atrophy and decreased thyroid secretion follow pituitary failure. Pituitary insufficiency may be caused by the destruction of thyrotrophs by either functioning or nonfunctioning pituitary tumors, surgical therapy, external pituitary radiation, postpartum pituitary necrosis (Sheehan's syndrome), trauma, and infiltrative processes of the pituitary such as metastatic tumors, tuberculosis, histiocytosis, and autoimmune mechanisms.[51] In all these situations, TSH deficiency most often occurs in association with other pituitary hormone deficiencies. The identification of secondary hypothyroidism due to bexarotene use has led to a recognition of the role of rexinoids and retinoids to cause dysregulation of TSH production.[52]

Note that pituitary enlargement in hypothyroidism does not invariably indicate the presence of a primary pituitary tumor. Pituitary enlargement is seen in patients with severe primary hypothyroidism due to compensatory hyperplasia and hypertrophy of the thyrotrophs. With thyroid hormone replacement therapy, serum TSH concentrations decline, indicating that the TSH secretion is not autonomous, and the pituitary resumes a more normal configuration. These patients are easily separated from patients with primary pituitary failure by measuring a TSH level.

Hypothalamic Disease

TRH deficiency also causes a rare form of secondary hypothyroidism (also referred to as tertiary hypothyroidism). In both adults and children, it may occur from cranial irradiation, trauma, infiltrative diseases, or neoplastic diseases.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Hypothyroidism

General

- Hypothyroidism can lead to a variety of end-organ effects with a wide range of disease severity, from entirely asymptomatic to coma with multisystem failure. In the adult, manifestations of hypothyroidism are nonspecific. In the child, thyroid hormone deficiency may manifest as delays in growth or intellectual development.
- Thyroid hormone is essential for normal growth and development during embryonic life. Uncorrected thyroid hormone deficiency during fetal and neonatal development results in mental retardation and/or cretinism. Both in children and adults, there is a slowing of physical and mental activity, as well as of cardiovascular, gastrointestinal, and neuromuscular function.

Symptoms

- Common symptoms of hypothyroidism include dry skin, cold intolerance, weight gain, constipation, and weakness.
- Complaints of lethargy, depression, fatigue, exercise intolerance, or loss of ambition and energy are also common but are less specific.
- Muscle cramps, myalgia, and stiffness are frequent complaints of hypothyroid patients.
- Menorrhagia and infertility may present commonly in women.

Signs

- Objective weakness is common, with proximal muscles being affected more than distal muscles. Slow relaxation of deep tendon reflexes is common.
- The most common signs of decreased levels of thyroid hormone include coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia.
- Speech is often slow, and the voice may be hoarse.
- Reversible neurologic syndromes such as carpal tunnel syndrome, polyneuropathy, and cerebellar dysfunction may also occur.
- Galactorrhea may be found in women.

Diagnosis

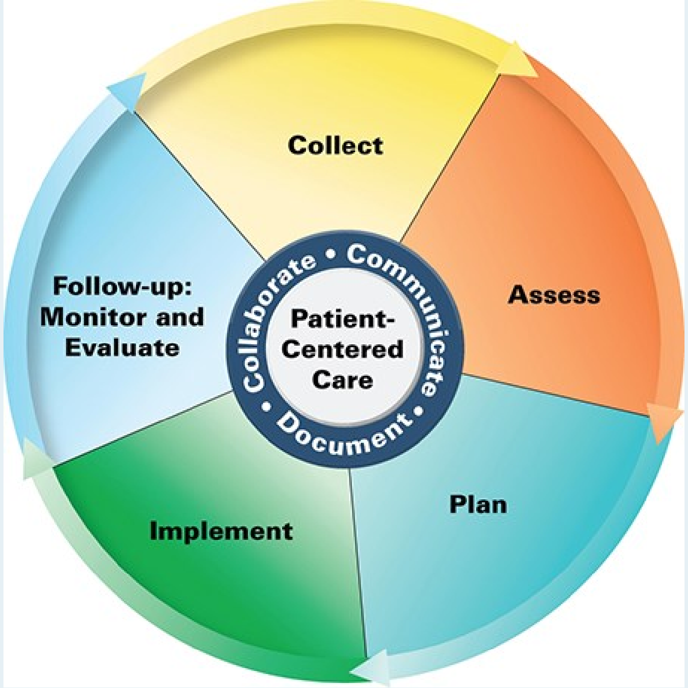
- A rise in the TSH is the first evidence of hypothyroidism in primary hypothyroidism.
- In secondary hypothyroidism in patients with pituitary disease, serum TSH concentrations are generally low or normal. A serum TSH concentration in the normal range is clearly inappropriate if the patient's T_4 is low.
- Many patients will have a free T_4 level within the normal range (compensated or subclinical hypothyroidism), with few, if any, symptoms of hypothyroidism. As the disease progresses, the free T_4 concentration will drop below the normal level. With increased TSH stimulation, thyroidal production will shift toward greater amounts of T_3, and thus T_3 concentrations will often be maintained in the normal range in spite of a low T4. Eventually, free and/or total T_4 and T_3 serum concentrations should be low.

Other Tests

- TPOAbs and anti-TG antibodies are likely to be elevated in autoimmune thyroiditis.

PATIENT CARE PROCESS

Patient Care Process for the Management of Hypothyroidism



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

The image shows the five fundamental steps included in The Pharmacist's Care Process endorsed by the Joint Commission for Pharmacy Practitioners (2014). The tagline of this process reads collaborate, communicate, and document. The five fundamental steps listed here are collect, assess, plan, implement, and follow-up: monitor and evaluate. All these steps are listed in a circular block diagram.

Collect

- Patient characteristics (eg, age, race, sex, pregnancy status)
- Patient history (past medical, family, social) including signs and symptoms: coarse skin and hair, cold or dry skin, periorbital puffiness, and bradycardia; cold intolerance, weight gain, constipation, weakness, muscle cramps, myalgia, and galactorrhea (see Clinical Presentation Box)
- Current medications (including OTC and herbal medication use)
- Objective data
    - Heart rate, BP, weight, and BMI
    - Labs (eg, TSH, FT_4, TT_3, anti-TG antibodies, TPO antibodies; serum electrolytes, Scr, ALT)
    - Other diagnostic tests when indicated (eg, thyroid ultrasound, RAIU scan)

Assess

- Cause of hypothyroidism (see Table 96-8)
- Current medications that may contribute to or worsen hypothyroidism
- Current medications that may interact with thyroid hormone replacement therapy

- Appropriateness and effectiveness of current thyroid hormone replacement regimen

Plan*

- Drug therapy regimen including specific thyroid hormone replacement therapy and dose (see Table 96-9)
- Monitoring parameters including efficacy (eg, resolution of signs and symptoms) and safety (arrhythmias, angina, osteoporosis, or symptomatic hyperthyroidism), laboratory data (TSH, FT_4, TT_3), and follow-up monitoring time frame
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, drug therapy)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up visits and laboratory tests

Follow-up: Monitor and Evaluate

- Resolution of signs and symptoms
- Presence of adverse effects
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Hypothyroidism

Most cases of hypothyroidism result from progressive and permanent damage to the thyroid gland. Replacement of thyroid hormone is the cornerstone of treatment.

Desired Outcomes

The goals of therapy are to restore normal thyroid hormone concentrations in tissue, provide symptomatic relief, prevent neurologic deficits in newborns and children, and reverse the biochemical abnormalities of hypothyroidism.

General Approach to Treatment

⑧ Levothyroxine (L-thyroxine, T_4) is considered to be the drug of choice for treatment of hypothyroidism (Table 96-9).[18] Other commercially available thyroid preparations can be obtained but are not considered preferred therapy. Available thyroid preparations are synthetic (L-thyroxine, liothyronine, and liotrix) or natural in origin (ie, desiccated thyroid). The preparations containing both T_4 and T_3 (liotrix, desiccated thyroid) have relatively high proportions of T_3 and may cause thyrotoxicosis.[18] Liothyronine is a short-acting preparation that requires dosing multiple times a day in order to achieve stable hormone concentrations. The availability of sensitive and specific assays for total and free hormone levels as well as TSH now allows precise dose titration to make adequate replacement without inadvertent overdose. The response of TSH to TRH had been advocated for use by some in order to “fine tune” thyroid replacement, but this is not necessary if the third-generation chemiluminometric assays for TSH, which have detection limits of about 0.01 mIU/L, are used. Clinical guidelines for the management of hypothyroidism have been published by the ATA and provide specific treatment recommendations and critically examine the use of combination therapy with T_4 and T_3[18] (Table 96-10).

TABLE 96-9

Thyroid Preparations Used in the Treatment of Hypothyroidism

Drug (Brand Name)	Dosage Form	Content	Relative Dose	Comments/Equivalency
• Thyroid USP • (Armour Thyroid, Nature-Throid, Westhroid, WP Thyroid) T_4:T_3 ratio approximately 4.2:1	Doses include 1/4, 1/2, 1, 2, 3, 4, and 5 grain tabletsArmour 1 grain = 60 mg; Nature-Throid and Westhroid, 1 grain = 65 mg.	Desiccated pork thyroid gland	1 grain (equivalent to 74 mcg of T_4)	High T_3:T_4 ratio; inexpensive
• Levothyroxine • (Euthyrox, Levoxyl, Synthroid,Unithroid,Tirosint, and Tirosint-SOL)	25, 50, 75, 88, 100, 112, 125, 137, 150, 175, 200, 300 mcg tablets Tirosint 13-150 mcg liquid in gelatin capsule Liquid solution: 13, 25, 50, 75, 88, 100, 112, 125, 137, 150, 175, and 200 mcg in unit-dose ampules injection: 200 and 500 mcg per vial	Synthetic T_4	100 mcg	Stable; predictable potency; generics may be bioequivalent; when switching from natural thyroid to L-thyroxine, lower dose by one-half grain; variable absorption between products; half-life = 7 days, so daily dosing; considered to be drug of choice
• Liothyronine • (Cytomel)	5, 25, and 50 mcg tablets	Synthetic T_3	33 mcg (~equivalent to 100 mcg T_4)	Uniform absorption, rapid onset; half-life = 1.5 days, rapid peak and troughs
• Liotrix • (Thyrolar)	1/4-, 1/2-, 1-, 2-, and 3-grain tablets	Synthetic T_4:T_3 in 4:1 ratio	Thyrolar 1 = 50 mcg T_4 and 12.5 mcg T_3 (~equivalent to 100 mcg T_4)	Stable; predictable; expensive; risk of T_3 thyrotoxicosis because of high ratio of T_3 relative to T_4

TABLE 96-10

Selected Recommendations from the American Thyroid Association Hypothyroidism Guidelines

Question	Synopsis or Paraphrase of Recommendation	Grading
Is levothyroxine monotherapy considered to be the standard of care for hypothyroidism?	Levothyroxine is recommended as the preparation of choice for the treatment of hypothyroidism due to its efficacy in resolving the symptoms of hypothyroidism.	Strong recommendation, moderate quality

What are the clinical and biochemical goals for levothyroxine replacement in primary hypothyroidism?	Levothyroxine replacement therapy has three main goals. These are (i) to provide resolution of the patients' symptoms and hypothyroid signs, (ii) to achieve normalization of serum thyrotropin, and (iii) to avoid overtreatment.	Strong recommendation, moderate quality
Are there situations in which therapy with levothyroxine dissolved in glycerin and supplied in gelatin capsules may have advantages over standard levothyroxine?	Although there are preliminary small studies suggesting that levothyroxine dissolved in glycerin and supplied in gelatin capsules may be better absorbed than standard levothyroxine, the present lack of controlled long-term outcome studies does not support a recommendation for the use of such preparations in these circumstances.	Weak recommendation, low quality
What factors determine the levothyroxine dose required by a hypothyroid patient for reaching the appropriate serum thyrotropin goal?	When deciding on a starting dose of levothyroxine, the patient's weight, lean body mass, pregnancy status, etiology of hypothyroidism, degree of thyrotropin elevation, age, and general clinical context should all be considered.	Strong recommendation, moderate quality
What is the best approach to initiating and adjusting levothyroxine therapy?	Thyroid hormone therapy should be initiated as an initial full replacement or as a partial replacement with gradual increments in the dose titrated upward using serum thyrotropin as the goal. Dose adjustments should be made, with thyrotropin assessment 4-6 weeks after any dosage change.	Strong recommendation, moderate quality
What approach should be taken in patients treated for hypothyroidism who have normal serum thyrotropin values but still have unresolved symptoms?	A minority of patients with hypothyroidism, but normal serum thyrotropin values, may perceive a suboptimal health status of unclear etiology. Acknowledgment of the patients' symptoms and evaluation for alternative causes is recommended in such cases.	Weak recommendation, low quality
In adults requiring thyroid hormone replacement treatment for primary hypothyroidism, is treatment with thyroid extracts superior to treatment with levothyroxine alone?	We recommend that levothyroxine be considered as routine care for patients with primary hypothyroidism, in preference to use of thyroid extracts. High-quality controlled long-term outcome data are lacking to document the superiority of this treatment compared to levothyroxine therapy.	Strong recommendation, moderate quality
In adults requiring thyroid hormone replacement treatment for primary hypothyroidism, is combination treatment including levothyroxine and liothyronine superior to the use of levothyroxine alone?	There is no consistently strong evidence of superiority of combination therapy over monotherapy with levothyroxine. Therefore, we recommend against the routine use of combination treatment with levothyroxine and liothyronine as a form of thyroid replacement therapy in patients with primary hypothyroidism.	Weak recommendation, moderate quality
In adults requiring thyroid hormone replacement treatment for primary hypothyroidism who feel unwell while taking levothyroxine, is combination treatment including levothyroxine and liothyronine superior to the use of levothyroxine alone?	For patients with primary hypothyroidism who feel unwell on levothyroxine therapy alone, there is currently insufficient evidence to support the routine use of a trial of a combination of levothyroxine and liothyronine therapy outside a formal clinical trial or N-of-1 trial, due to uncertainty in the long-term risk-benefit ratio of the treatment.	Insufficient evidence
Are there data regarding therapy with triiodothyronine alone, either as standard liothyronine or as sustained release triiodothyronine, that support the use of triiodothyronine therapy alone for the treatment of hypothyroidism?	Although short-term outcome data in hypothyroid patients suggest that thrice-daily synthetic liothyronine may be associated with beneficial effects on parameters such as weight and lipids, longer-term controlled clinical trials are needed before considering synthetic liothyronine therapy for routine clinical use.	Strong recommendation, moderate quality

Data from Reference [10].

Strong recommendation: Benefits clearly outweigh risks and burden, or risks and burden clearly outweigh benefits. Weak recommendation: Benefits finely balanced with risks and burden. Quality of evidence: High, moderate, or low.

Pharmacologic Therapy

Levothyroxine is the drug of choice for thyroid replacement and suppressive therapy because it is chemically stable, relatively inexpensive, active when orally administered, free of antigenicity, and has uniform potency. Levothyroxine (T_4) administration results in a pool of thyroid hormones that is readily converted to T_3 when needed; in this regard, levothyroxine may be thought of as a prohormone.

Liothyronine (T_3) is chemically pure with a known potency and has a shorter half-life of 1.5 days. Although it can be used diagnostically in the T_3 suppression test, T_3 has some clinical disadvantages, including a higher incidence of cardiac adverse effects, higher cost, and difficulty in monitoring with conventional laboratory tests. If used, T_3 needs to be administered three times a day and it may take a prolonged period of adjustment to achieve stable euthyroidism. Liotrix is a combination of synthetic T_4 and T_3 in a 4:1 ratio. It is chemically stable and pure and has a predictable potency. The major limitations to this product are high cost and lack of therapeutic rationale because most T_3 is peripherally converted from T_4. In addition, the T_4:T_3 ratio is much higher than the 14:1 molar ratio produced by the thyroid gland in humans.

⑨ The use of combination therapy of levothyroxine and liothyronine remains highly controversial with conflicting results from clinical trials.[53] The American Thyroid Association, British Thyroid Association, and European Thyroid Association reviewed the latest basic science and clinical evidence regarding thyroid hormone combination therapy and published a position statement to guide the design of future clinical trials of T_4/T_3 therapy.[54] A well-designed, adequately powered clinical trial of combination therapy in patients dissatisfied with levothyroxine replacement therapy is anticipated.

A study conducted in rats suggested impairment of type 2 deiodinase activity in the whole body during levothyroxine monotherapy due to deiodinase inactivation, compared with maintenance of deiodinase activity in the hypothalamus.[55] The lesser activation in the hypothalamus leads to efficient T_3 production in the hypothalamus and normalization of TSH before T_3 is normalized in the rest of the body. Accompanying the inactivation of type 2 deiodinase in other tissues, lower serum T_3 and higher T_4/T_3 ratios were seen in rats during monotherapy with L-thyroxine, compared with combination therapy employing a subcutaneous slow-release T_3 pellet. Clinical trials of a slow-release T_3 preparation, other than a pharmacokinetic study of T_3 sulfate in profoundly hypothyroid individuals,[56] has yet to be conducted.

Desiccated thyroid has historically been derived from pig, beef, or sheep thyroid glands, although pigs are currently the usual source. The United States Pharmacopeia requires thyroid USP to contain 38 mcg (±15%) of L-thyroxine and 9 mcg (±10%) of liothyronine for each 60 to 65 mg (one grain). Thyroid USP, as an animal protein-derived product, may be antigenic in allergic or sensitive patients. Even though desiccated thyroid is inexpensive, its limitations preclude it from being considered as a drug of choice for hypothyroid patients.

Pharmacokinetics

The half-life of levothyroxine is approximately 7 days. This long half-life is responsible for a stable pool of prohormone and the need for only once-daily dosing with levothyroxine. Older studies with levothyroxine suggested that bioavailability was low and erratic; however, this product has been reformulated, and the average bioavailability improved to approximately 80%. Different levothyroxine preparations contain different excipients such as dyes and fillers. However, because the relationship between T_4 concentration and TSH is not linear, very small changes in T_4 concentration can lead to substantial changes in TSH, which is a more accurate reflection of hormone replacement status. The FDA mandates that L-thyroxine bioequivalency testing be done using normal volunteers (600 mcg in the fasted state) and three baseline free T_4 concentrations be used to correct for endogenous T_4 production. Bioequivalency is based on the area under the curve (AUC) and maximum concentration (C_{max}) of T_4 out to 48 hours. Approximately 70% of the AUC is derived from endogenous production. TSH is not considered, and it is now very clear that T_4 is too insensitive as a measure of bioequivalency.[57] To avoid overtreatment and undertreatment, once a product is selected, switches between levothyroxine products in patients who are stable are not recommended. Several levothyroxine products are available, including AB1, AB2, AB3, and AB4 rated products. This has created several permutations for product interchangeability since no reference drug is mandated in bioequivalency testing.

Adverse Effects

Serious untoward effects are unusual if dosing is appropriate and the patient is carefully monitored during the initial treatment. Suboptimal thyroid hormone therapy including under-replacement and over-replacement is common among patients with hypothyroidism.[58] Levothyroxine replacement in athyreotic hypothyroid patients restores systolic and diastolic left ventricular performance within 2 weeks, and the use of levothyroxine may increase the frequency of atrial premature beats but not necessarily ventricular premature beats. Excessive doses of thyroid hormone may lead to heart failure, atrial fibrillation, angina pectoris, and myocardial infarction; rarely, the latter may be caused by coronary artery spasm. Allergic or idiosyncratic reactions can occur with natural animal-derived products such as desiccated thyroid, but these are extremely rare with the synthetic products used today. The 0.05 mg (50 mcg) Synthroid tablet is the least allergenic (due to a lack of dye and few excipients) and should be tried for the patient suspected to be allergic to thyroid hormone tablets.

Hyper-remodeling of cortical and trabecular bone due to hyperthyroidism leads to reduced bone density and may increase the risk of fracture. Compared with normal controls, excess exogenous thyroid hormone results in histomorphometric and biochemical changes similar to those observed in osteoporosis and untreated hyperthyroidism.[59] The risk for this complication seems to be related to the dose of levothyroxine, patient age, and gender. Markers for bone turnover include urinary *N*-telopeptides, pyridinoline crosslinks of type I collagen, osteocalcin, procollagen type 1 N-terminal propeptide, and bone-specific alkaline phosphatase. When doses of levothyroxine are used to suppress TSH concentrations to below-normal values (eg, less than 0.3 mIU/L) in postmenopausal women, this adverse effect is more likely to be seen. Cortical bone is affected to a greater degree than trabecular bone at suppressive doses of L-thyroxine. In contrast, it appears to be much less likely in men and in premenopausal women. Maintaining the TSH between 0.7 and 1.5 mIU/L does not alter bone mineral density in premenopausal women. Although not all studies have shown consistent results, a cohort study suggests that treatment with L-thyroxine to achieve a normal TSH has no adverse effect on bone density.[60]

Drug-Drug and Drug-Food Interactions

The time to maximal absorption of levothyroxine is about 2 hours and this should be considered when T_4 concentrations are determined. Ingestion of L-thyroxine with food can impair its absorption.[18] This can potentially affect the TSH concentration achieved if levothyroxine timing with respect to food is varied. Mucosal diseases, such as celiac sprue, diabetic diarrhea, and ileal bypass surgery, can also reduce absorption. Cholestyramine, calcium carbonate, sucralfate, aluminum hydroxide, ferrous sulfate, soybean formula, dietary fiber supplements, and espresso coffee may also impair the absorption of levothyroxine from the gastrointestinal tract (reviewed extensively in recent hypothyroidism guidelines[18]). Acid suppression with histamine blockers and proton pump inhibitors may also reduce levothyroxine absorption. Drugs that increase nondeiodinative T_4 clearance include rifampin, carbamazepine, and possibly phenytoin. Selenium deficiency and amiodarone may block the conversion of T_4 to T_3.

Several non-randomized studies have suggested that liquid formulations of levothyroxine or formulations in which the levothyroxine is dissolved in glycerin and encased in a gelatin capsule may circumvent the impaired absorption of levothyroxine that may occur with tablet preparations.[61] For patients receiving enteral feeding, liquid levothyroxine added directly to the feeding tube was associated with a similar serum TSH to that seen in another group of patients in whom the feeding was interrupted in order to administer crushed tablets.[62] The former procedure was found to be more convenient by providers. In a study of patients taking proton pump inhibitors, switching to an oral solution was associated with a decrease in serum TSH from a mean of 5.4 to 1.7 mIU/L, suggesting better absorption of the liquid preparation in these patients.[63] A study of patients with gastritis who had a stable serum TSH while taking levothyroxine tablets and were then switched to a lower dose of levothyroxine gel capsules showed that two-thirds of patients had a similar TSH on the lower dose, again suggesting better absorption of the gel capsule formulation.[64] In a double-blind, randomized, crossover trial of liquid thyroxine in 77 treatment-naive patients with hypothyroidism, no significant differences in thyroid function tests were seen when the liquid preparation was ingested at breakfast or 30 minutes before breakfast.[65] This could provide a solution for patients with difficulties ingesting levothyroxine before breakfast. If the findings of these studies are bolstered by randomized controlled studies in the future, these levothyroxine formulations may prove very convenient for hypothyroid patients. Alternatively, studies in adults with hypothyroidism suggest an equal efficacy of bedtime versus early morning intake of levothyroxine.[66]

Dosing and Administration

The average maintenance dose of levothyroxine for most adults is about 125 mcg/day.[53] The replacement dose of levothyroxine is affected by body weight. Estimates of weight-based doses for replacement in hypothyroid patients without any autonomous thyroid function include 1.6 and 1.7 mcg/kg/day, though hypothyroid patients still producing some thyroid hormone will require lower doses.[18] There is, however, a wide range of replacement doses, necessitating individualized therapy and appropriate TSH monitoring to determine an adequate but not excessive dose.

In addition to alleviation of symptoms, the goal of treatment for patients with hypothyroidism is to maintain the patient's TSH within the normal range. Some clinicians are of the opinion that the traditional reference range of approximately 0.5 to 4.5 mIU/L includes at its upper end some individuals who have unrecognized thyroid disease. Thus, some believe that the reference range should be modified downward to 0.5 to 3.5 mIU/L or even 0.5 to 2.5 mIU/L.[67] If this premise is accepted, both the TSH values that trigger L-thyroxine treatment and the TSH treatment goal could potentially be altered. There are cogent arguments on both sides of the issue. Those who suggest maintaining current reference ranges believe that lowering the upper limit of the reference range could result in treating many individuals with thyroid hormone who would not necessarily benefit from such treatment.[68] Those who favor narrowing the reference range suggest that additional patients would, in fact, derive benefit from thyroid hormone treatment.[67] There are calls by some for increasing the thyrotropin reference range specifically among individuals aged 80 years and older.[69] TSH reference ranges also differ for different populations, such as those who are pregnant, specific ethnic groups, and older individuals.[18]

The required dose of levothyroxine is dependent on the patient's age and the presence of associated disorders, as well as the severity and duration of hypothyroidism.[18] Most patients devoid of any thyroid function will require approximately 1.7 mcg/kg/day once they reach steady-state for full replacement. Dose requirement may be better estimated based on ideal body weight, rather than actual body weight. In patients with long-standing disease and older individuals without known cardiac disease, therapy should be initiated with 50 mcg daily of levothyroxine and increased after 1 month. The recommended initial daily dose for older patients with known cardiac disease is 25 mcg daily titrated upward in increments of 25 mcg at monthly intervals to prevent stress on the cardiovascular system. Some patients may experience an exacerbation of angina with higher doses of thyroid hormone. Although TSH is an indicator of under-replacement or over-replacement, clinicians often fail to alter the dose based on TSH values clearly outside of the normal range.

Subclinical hypothyroidism is a laboratory-defined phenomenon in which a patient has an elevated TSH level in the presence of a normal FT_4 level. Patients with subclinical hypothyroidism often complain of symptoms commonly seen in patients with overt hypothyroidism such as cold insensitivity, dry skin, fatigue, constipation, muscle cramps, poor memory, slowed thinking, and depression. However, up to a quarter of people with normal TSH levels report up to two of these symptoms, pointing to the nonspecific nature of these symptoms. An estimated 13 million people in the United States have subclinical hypothyroidism. Subclinical hypothyroidism progresses to overt hypothyroidism in 2% to 5% of patients per year.[70] The risk of progression is significantly greater in individuals with antibodies to thyroid peroxidase (TPO) and in those with higher baseline TSH levels. Levothyroxine therapy was not associated with a significant improvement in hypothyroid symptoms, fatigue, or quality-of-life in patients age 80 years or older with subclinical hypothyroidism.[71] These results argue against the routine use of levothyroxine for the treatment of subclinical hypothyroidism, particularly in the elderly. Thyroid hormone therapy was associated with lowering the mean thyrotropin value into the normal reference range compared with placebo but was not associated with improvements in general quality of life or thyroid-related symptoms.[72] While most patients with subclinical hypothyroidism can be observed without treatment, treatment may be indicated for patients with subclinical hypothyroidism and serum thyrotropin levels of 10 mU/L or higher, or for young and middle-aged individuals with subclinical hypothyroidism and symptoms consistent with mild hypothyroidism.[70]

Once euthyroidism is attained, the daily maintenance dose of levothyroxine does not fluctuate greatly. As patients age, the dosing requirement may be reduced.[18] Third-generation TSH assays improved the accuracy with which thyroid hormone replacement can be monitored. The TSH concentration is the most sensitive and specific monitoring parameter for adjustment of levothyroxine dose. Plasma TSH concentrations begin to fall within hours and are usually normalized within 2 weeks, but they may take up to 6 weeks for some patients, depending on the baseline value. Both TSH and T_4 concentrations are used to monitor therapy, and they should be checked every 6 weeks until a euthyroid state is achieved.[18] Laboratory assessment of thyroid function should be performed approximately 6 weeks after levothyroxine dose initiation or change. This time frame allows achievement of steady-state, as the half-life of levothyroxine is approximately 1 week. Serum T_4 concentrations can be useful in detecting noncompliance, malabsorption, or changes in levothyroxine product bioequivalence, among other things.[73] An elevated TSH concentration indicates insufficient replacement. The appropriate dose maintains the TSH concentration in the normal range. T_4 disposal is accelerated by nephrotic syndrome, other severe systemic illnesses, and several antiseizure medications (phenobarbital, phenytoin, and carbamazepine) and rifampin. Pregnancy increases the T_4 dose requirement for 75% of women, probably because of factors such as increased degradation by the placental deiodinase, increased T_4 pool size, and transfer of T_4 to the fetus. The etiology of hypothyroidism also affects the magnitude of the dosage increase. Initiating postmenopausal hormone replacement therapy increases the dose needed in 35% of women, perhaps due to an increased circulating TBG level. Patient noncompliance with prescribed T_4, the most common cause of inadequate treatment, might be suspected for patients with a dose that is higher than expected, variable thyroid function test results that do not correlate well with prescribed doses, and an elevated serum TSH concentration with serum-free T_4 at the upper end of the normal range, which can suggest improved compliance immediately before testing, with a lag in the thyrotropin response.

For patients with central hypothyroidism caused by hypothalamic or pituitary failure, the serum TSH cannot be used to assess the adequacy of replacement. Alleviation of the clinical syndrome and restoration of serum T_4 to the normal range are the only criteria available for estimating the appropriate replacement dose of L-thyroxine. Keeping free T_4 values in the upper part of the normal laboratory reference range is a reasonable approach, with modification of this goal to the middle of the normal range in older patients or patients with comorbidities. Concurrent use of dopamine, dopaminergic agents (bromocriptine), somatostatin or somatostatin analogs (octreotide), and corticosteroids suppresses TSH concentrations in individuals with primary hypothyroidism and may confound the interpretation of this monitoring parameter.[18]

TSH-suppressive levothyroxine therapy can be given to patients with nodular thyroid disease and diffuse goiter, and to patients with a history of thyroid irradiation. It is also usually given to patients with papillary or follicular thyroid cancer. The rationale for suppression therapy is to reduce TSH secretion, which promotes the growth and function of abnormal thyroid tissue. However, such management, other than for patients with thyroid cancer or with elevated TSH levels, is quite controversial. Some clinicians rarely recommend or use such therapy; others will recommend a trial of levothyroxine as suppressive therapy in some patients. Three meta-analyses concluded that suppressive therapy for nodules was associated with a small decrease in nodule growth, a nonsignificant reduction in nodule growth, and a significant reduction in nodule growth with longer-term treatment. L-Thyroxine may be given in nontoxic MNG to suppress the TSH to low- normal levels of 0.5 to 1 mIU/L if the baseline TSH is more than 1 mIU/L. Goiter size and thyroid volume may be reduced with suppression therapy. Diffuse goiter associated with autoimmune thyroiditis may also be treated with levothyroxine to reduce goiter size and thyroid volume. If suppressive therapy with levothyroxine is pursued, the age, gender, and menopausal status of the patient need to be considered, along with the risk of cardiac arrhythmias and reduced bone mineral density. Levothyroxine suppression therapy is of benefit to all but the lowest-risk thyroid cancer patients and is generally used in the management of patients with differentiated thyroid cancer, with the TSH goal being influenced by the patient's thyroid cancer stage and other risk factors. Current guidelines from the ATA suggest suppressing the TSH to below 0.1 mIU/L in higher-risk patients but keeping TSH around the lower limit of normal (0.1-0.5 mIU/L) in low-risk patients.[74]

Special Populations

Myxedema Coma

Myxedema coma is a rare consequence of decompensated hypothyroidism.[8] Clinical features include hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy. Traditionally, the initial treatment has been IV bolus levothyroxine 300 to 500 mcg.[18] However, as deiodinase activity is markedly reduced, impairing T_4 to T_3 conversion, initial treatment with IV T_3, or a combination of both hormones, has also been advocated.[8] Glucocorticoid therapy with IV hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out.[18] All therapies must be administered parenterally as cessation of gastrointestinal peristalsis occurs, preventing the absorption of orally administered medications. Consciousness, lowered TSH concentrations, and improvement in vital signs are expected within 24 hours. Maintenance doses of levothyroxine are typically 75 to 100 mcg given IV until the patient stabilizes and oral therapy is begun. Supportive therapy must be instituted to maintain adequate ventilation, BP, and body temperature, and ensure euglycemia. Any underlying disorder which may have precipitated the event, such as sepsis or myocardial infarction, obviously must be diagnosed and treated.

Congenital Hypothyroidism

In congenital hypothyroidism, full maintenance therapy should be instituted early to improve the prognosis for mental and physical development. The average maintenance dose in infants and children depends on the age and weight of the child. Several studies demonstrate that aggressive therapy with levothyroxine is important for normal development, and current recommendations are for initiation of therapy as soon as possible after birth at a dose of 10 to 15 mcg/kg/day. This dose is used to keep T_4 concentrations at about 10 mcg/dL (130 nmol/L) within 30 days of starting therapy and is associated with improved IQs. The dose is progressively decreased to a typical adult dose as the child ages, with the adult dose given starting in puberty.

Hypothyroidism During Pregnancy

Hypothyroidism during pregnancy leads to an increased rate of stillbirths and possibly lower neuropsychological scores in infants born of women who received inadequate replacement during pregnancy.[38] Thyroid hormone is necessary for fetal growth and must come from the maternal side during the first 2 months of gestation. Although liothyronine may cross the placental membrane slightly better than levothyroxine, the latter is considered the drug of choice. The objective of treatment is to decrease TSH to normal, based on the normal reference range for pregnancy. Current guidelines suggest a TSH below 2.5 mIU/L during the first trimester and a TSH below 3 mIU/L during the remainder of the pregnancy.[38] Based on elevated TSH levels during pregnancy, the mean dose of levothyroxine had to be increased by 48% to decrease TSH into the normal range. However, in individual women, the dosage increase needed may vary from approximately 10% to 80%. Increased production of binding proteins, a marginal decrease in free hormone concentration, modification of peripheral thyroid hormone metabolism, and increased T_4 metabolism by the fetal-placental unit all may contribute to increased thyroid hormone demand. As these changes regress after delivery, the need for increased levothyroxine will decline.[38] Up to 60% of women need to have levothyroxine dose adjustment during pregnancy. An upward adjustment in the dose will usually be needed by the eighth week of pregnancy. Current guidelines recommend that hypothyroid patients receiving levothyroxine who become pregnant should increase their levothyroxine dose by 20% to 30% (two additional tablets weekly) as soon as they know they are pregnant.[38] After delivery the levothyroxine dose can be reduced based on T_4 concentrations and measurement of TSH, typically about 6 to 8 weeks after delivery. Many patients can return to their pre-pregnancy dose requirement.

EVALUATION OF THERAPEUTIC OUTCOMES—HYPOTHYROIDISM

Patients with idiopathic hypothyroidism and Hashimoto’s thyroiditis on optimal thyroid hormone replacement therapy should have TSH and free T_4 serum concentrations in the normal range.[18] Those who are being treated for thyroid cancer should have TSH suppressed to low levels, with the appropriate TSH concentration being determined based on the patient’s risk of recurrence or progression, and TG levels should be undetectable.[74] Given the 7-day half-life of T_4 and the potential delayed response of the hypothalamus, the appropriate monitoring interval for follow-up thyroid function testing is no more frequent than every 4 to 6 weeks. The signs and symptoms of hypothyroidism should be improved or absent (see Clinical Presentation of Hypothyroidism discussed earlier), although it may take several months for the full benefit of therapy to manifest.

CONCLUSION

Hypothyroidism is a common disorder but if left untreated it can progress into myxedema coma in the absence of an adequate endogenous thyroid reserve. Levothyroxine is a readily available and highly effective treatment that rapidly reverses the biochemical and clinical abnormalities that characterize hypothyroidism. Serum TSH and thyroid hormone levels are useful measures for adjusting the levothyroxine dose.

ABBREVIATIONS

anti-TPO Ab	anti-thyroid peroxidase antibody
ATD	antithyroid drug

AUC	area under the curve
BMI	body mass index
BP	blood pressure
cGy	centigray
C_{max}	maximum concentration
ClO_4^-	perchlorate
CNS	central nervous system
DIT	diiodotyrosine
FSH	follicle-stimulating hormone
FT_3	free triiodothyronine
FT_4	free thyroxine
Gsα	the α subunit of the stimulatory guanine-nucleotide–binding protein
hCG	human chorionic gonadotropin
HLA	human leukocyte antigen
^{131}I	sodium iodide-131
L-thyroxine	levothyroxine
LH	luteinizing hormone
MIT	monoiodotyrosine
MMI	methimazole
MNG	multinodular goiter
NHANES III	Third National Health and Nutrition Examination Survey
OTC	over the counter
PRTH	pituitary resistance to thyroid hormone
PTU	propylthiouracil
RAI	radioactive iodine
RAIU	radioactive iodine uptake

rT_3	reverse triiodothyronine
SCN^-	thiocyanate
SSKI	saturated solution of potassium iodide
T_3	triiodothyronine
T_4	thyroxine
TBG	thyroxine-binding globulin
TBII	TSH binding inhibitor immunoglobulin
TBPA	thyroid-binding prealbumin
TcO_4^-	pertechnetate
TG	thyroglobulin
TPOAb	thyroid peroxidase antibodies
TR	thyroid hormone receptor
TRH	thyrotropin-releasing hormone
TRIAC	triiodothyroacetic acid
TSAb	thyroid-stimulating antibody
TSH	thyroid-stimulating hormone
TT_3	total triiodothyronine
TT_4	total thyroxine
TTR	transthyretin
WBC	white blood cell

SELF ASSESSMENT QUESTIONS

1. Which of the following signs or symptoms would lead you to suspect hyperthyroidism in a patient you are evaluating?

   A. Constipation

   B. Weight gain

   C. Depression

   D. Increased anxiety

2. Which of the following signs or symptoms would lead you to suspect hypothyroidism in a patient you are evaluating?

   A. Cold intolerance

   B. Increased appetite

   C. Palpitations

   D. Hyperreflexia

3. In a patient with primary hypothyroidism, which of the following thyroid function test results would you expect to find?

   A. Low FT_4, TT_3, and TSH levels

   B. Elevated FT_4, TT_3, and TSH levels

   C. Low FT_4 and TT_3 levels and elevated TSH levels

   D. Elevated FT_4 and TT_3 levels and low TSH levels

4. A cause of hyperthyroidism associated with a low radioactive iodine uptake (RAIU) scan is

   A. Graves' disease.

   B. Multinodular goiter.

   C. Thyroiditis.

   D. Toxic adenoma.

5. An otherwise well 43-year-old woman with recently diagnosed Graves' disease has decided to receive RAI therapy to definitively treat her hyperthyroidism. During the next 6 to 8 weeks prior to therapy, which of the following therapies is best avoided?

   A. A nonselective β-blocker

   B. Lugol's solution

   C. Methimazole

   D. Nadolol

6. Fred is a 40-year-old male who opts to receive drug therapy for the management of his hyperthyroidism secondary to a toxic multinodular goiter. Which of the following choices is the best therapy for his management?

   A. Lugol's solution 5 drops po TID

B. SSKI 3 drops po TID

C. Methimazole 10 mg po BID

D. PTU 100 mg po TID

7. Terry is a 59-year-old Caucasian female who has been treated with thyroid hormone replacement therapy for the last ten years for Hashimoto's thyroiditis. She states that she always takes her thyroid medication with breakfast and her refill records show that she always refills her T_4 on the 30th of the month. She has no other pertinent medical history. Two months ago she started medication for iron- deficiency anemia (iron sulfate 325 mg po TID with meals). Today's TSH level is 28 mIU/L(Reference Range: 0.4-4.0 mIU/L) despite her regular Synthroid dose of 125 mcg orally each morning. The most likely explanation of this patient's laboratory findings is

A. Noncompliance

B. Drug interaction.

C. Pregnancy.

D. Improper diagnosis.

8. George is a 46-year-old male with hyperthyroidism due to Graves' disease who has opted for methimazole therapy for management. The most important counseling advice he should receive is that

A. He has an approximate 33% chance of long-term remission of disease.

B. Methimazole is a better choice than PTU because of less hepatotoxicity.

C. Get a WBC count at the first sign of infection.

D. Take the medicine with food to minimize gastrointestinal upset.

9. Dotty is a 74-year-old, obese (100 kg) Caucasian female with a history of T2DM, hypertension, hyperlipidemia, atrial fibrillation, and coronary artery disease, who was recently diagnosed with hypothyroidism (numerous symptoms; FT_4 of 0.65 ng/dL (Reference Range: 0.7-1.9 ng/dL) or 8.4 pmol/L (Reference Range: 9-24.5 pmol/L); and a TSH of 43.4 mIU/L (Reference Range: 0.4-4.0 mIU/L) due to Hashimoto's thyroiditis. Her best initial thyroid hormone replacement strategy is

A. Armor Thyroid 3 grains orally once daily.

B. Cytomel 50 mcg orally twice/day.

C. Synthroid 175 mcg orally daily.

D. Tirosint 50 mcg orally daily.

10. Lucy is a 38-year-old woman with newly diagnosed Graves' disease, who experiences fatigue, heat intolerance, tremor, and palpitations. She has no significant medical history and is currently taking no medications. Laboratory results include the following: TSH less than 0.01 mIU/L (Reference Range: 0.4-4.0 mIU/L); FT_4 3.3 ng/dL (Reference Range:0.7-1.9 ng/dL) or 42.5 pmol/L (Reference Range: 9-24.5 pmol/L); and TT_3 368 ng/dL (Reference Range:80-180 ng/dL) or 5.67 nmol/L (Reference Range: 1.23-2.77 nmol/L). Initiation of which one of the following regimens will reduce her symptoms within hours?

A. PTU 100 mg three times/day

B. Methimazole 10 mg two times/day

C. Lugol's solution 10 drops three times/day

D. Nadolol 40 mg two times/day

11. Which of the following statements is true regarding liothyronine (synthetic T_3)?

    A. It has a half-life of about one hour.

    B. It is the treatment of choice for hypothyroidism.

    C. It produces stable serum levels of both T_4 and T_3.

    D. The side effects can include palpitations and insomnia.

12. Maggy is a 44-year-old woman with a history of papillary thyroid cancer who has always received the same generic levothyroxine replacement preparation since her thyroidectomy 4 years ago. Why is it important that she continue to receive the same T_4 preparation?

    A. So she can save money.

    B. So she won't need as many repeat thyroid function tests performed.

    C. So she can maintain consistent TSH levels, which is important in reducing her risk of cancer recurrence.

    D. She shouldn't continue on a generic; she should be switched to a branded T_4 preparation as this is a narrow therapeutic index drug.

13. Susan is a 40-year-old, 70-kg woman recently diagnosed with hypothyroidism (HoTR) due to Hashimoto's disease. She originally started levothyroxine 50 mcg orally once daily for 3 weeks, and for the last 2 weeks has received 100 mcg daily. The results of today's thyroid function tests (TFTs) are as follows: total thyroxine (TT_4) 3.5 mcg/dL (Reference Range: 5-12 mcg/dL) or 45 nmol/L (Reference Range: 64-154 nmol/L)], total triiodothyronine (TT_3) 56 ng/dL (Reference Range: 80-180 ng/dL) or 0.86 nmol/L (Reference Range: 1.23-2.77 nmol/L), and thyroid-stimulating hormone (TSH) 28 mIU/L (Reference Range: 0.4-4.0 mIU/L). Given these laboratory test results, which is the best recommendation for Susan's thyroxine (T_4) dose?

    A. Decrease her dose because her TSH level is high.

    B. Increase her dose because her total T_4 (TT_4) and total T_3 (TT_3) values are low.

    C. Make no change because steady state has not been reached on this dose.

    D. Make no change because her free T_4 (FT_4) value is not available.

14. Which of the following therapies is *inappropriate* for the treatment of thyroid storm?

    A. Administering a β-blocker as initial therapy

    B. Administering SSKI as initial therapy

    C. Administering PTU as initial therapy

    D. Administering methylprednisolone as initial therapy

15. Which of the following statements is true regarding the treatment of myxedema coma?

    A. High-dose oral liothyronine is most effective.

    B. Oral levothyroxine is the mainstay of therapy.

C. β-Blockers are routinely administered.

D. Intravenous thyroid hormone replacement is advisable.

SELF-ASSESSMENT QUESTIONS-ANSWERS

1. **D.** Hyperthyroidism represents a hypermetabolic state. The typical clinical manifestations of thyrotoxicosis include nervousness, anxiety (answer D), palpitations, easy fatigability, menstrual disturbances, and heat intolerance. A cardinal sign is a loss of weight concurrent with an increased appetite. Constipation, weight gain, and depression (choices A, B, and C) are common manifestations of hypothyroidism. See Clinical Presentation—Thyrotoxicosis.

2. **A.** Hypothyroidism represents a hypometabolic state, with typical signs and symptoms including dry skin, cold intolerance (answer A), weight gain, constipation, and weakness. Complaints of lethargy, depression, fatigue, exercise intolerance, or loss of ambition and energy are also common but are less specific. Increased appetite, palpitations, and hyperreflexia (choices B, C, and D) are common manifestations of hyperthyroidism. See Clinical Presentation—Hypothyroidism.

3. **C.** Primary hypothyroidism refers to a lack of thyroid hormone synthesis as a result of loss of function of the thyroid gland itself. This results in low FT_4 and TT_3 levels. Consequently, TRH and TSH secretion is increased in an attempt to stimulate the failing thyroid gland to make more T_3 and T_4. Therefore, answer C is correct. See Table 92-4.

4. **C.** A radioactive iodine uptake (RAIU) tests thyroid function by measuring how much radioactive iodine is taken up by the thyroid gland over a certain time period (6 hours and 24 hours). This test is often ordered for patients with symptoms of thyrotoxicosis to help identify the specific cause of hyperthyroidism. Causes of thyrotoxicosis associated with an elevated RAIU include Graves' disease, multinodular goiter, toxic adenoma (choices A, B, and D), trophoblastic diseases, and a TSH-secreting tumor. Common causes of thyrotoxicosis associated with a low RAIU include thyroiditis (answer C), iodide ingestion, and ingestion of exogenous thyroid hormone. See text under Causes of Thyrotoxicosis Associated with Suppressed RAIU.

5. **B.** Most hyperthyroid patients opting for definitive therapy (surgery, RAI) will be pretreated for 6 to 8 weeks prior to the procedure to reduce HTR symptoms and to prevent thyroid storm as a result of the definitive procedure. All of the listed choices are potential treatments for Graves' disease. Nadolol (choice D) is a non-selective β-blocker (choice A) and is associated with prompt (within hours) reduction of many hyperthyroid symptoms and will not interfere with RAI therapy. Methimazole (choice C) is a thioamide and inhibits organification and coupling but does not affect stored thyroid hormone values; thus, several weeks are required before a reduction in HTR symptoms is evident. It is generally used for 6 to 8 weeks prior to surgery or RAI and then stopped 3 to 4 days prior to RAI therapy. Lugol's solution (Answer B) contains iodide; iodides given prior to RAI therapy will prevent uptake of the RAI by the thyroid gland (Wolff–Chaikoff mechanism), rendering its use ineffective.

6. **C.** Iodide therapy (choices A and B) is used to decrease the release of stored thyroid hormone but is not used in patients with autonomous thyroid disorders (uninodular or multinodular disease) as these tissues will subsequently use the iodine to make new thyroid hormone, further exacerbating the hyperthyroidism. Thioamides decrease the production of new thyroid hormones by inhibiting organification and coupling. Methimazole (choice C) is preferred over propylthiouracil (PTU) because of the decreased incidence of hepatotoxicity.

7. **B.** The patient has a 10-year history of thyroid disease, dutifully picks up prescriptions each month, and is 59 years old, thereby making choices A, C, and D unlikely. Levothyroxine is approximately 80% bioavailable but its absorption can be decreased by food and medications. Di- and trivalent cations (calcium, magnesium, aluminum, iron) are well known to markedly decrease the absorption of T_4 unless the T_4 is taken 1 hour prior or at least 4 hours after the interacting medication. The patient has been taking her T_4 and morning iron dose together for the last two months and now has an elevated TSH level, making choice B the correct answer.

8. **C.** All of the above choices are correct statements. However, choice C is the best answer as there is the possibility of life-threatening drug-induced agranulocytosis with the use of thioamide therapy. Patients should be advised to have a white blood cell (WBC) count with differential performed at the first sign of an infection (sore throat, fever) to rule out agranulocytosis after starting thioamide therapy.

9. **D.** T_4 is the generally recommended thyroid hormone of choice as it is stable, pure, and has predictable potency; serum T_3 concentration is controlled physiologically (less likelihood of HTR-like adverse effects compared with T_3 formulations or T_4/T_3 combination products); and it has a long

half-life, allowing once-daily dosing. The typical maintenance dose of T_4 required in patients without endogenous thyroid function is approximately 1.6 to 1.7 mcg/kg. However, replacement therapy is typically initiated at a lower dose to minimize the risk of untoward events, such as precipitation of arrhythmias or cardiac ischemia. The four choices listed are equivalent to approximately 180, 240, 175, and 50 mcg of T_4, respectively. As this patient has a history of atrial fibrillation and coronary artery disease, a modest dose of T_4 should be initiated and then titrated as tolerated, making choice D the correct answer.

10. **D.** It takes weeks for thioamides (answers A and B) to have an effect because they inhibit the formation of new thyroid hormone but do nothing to reduce stored thyroid hormone levels. Lugol's solution (Answer C) inhibits the release of stored thyroid hormone. Symptom relief is seen much sooner than with the thioamides but only after circulating thyroid hormone values significantly decrease (T_4 half-life is about 7 days in a euthyroid patient). β-Blockers begin to manage sympathetic-mediated symptoms immediately.

11. **D.** Liothyronine has a half-life of approximately one day (not 1 hour), it is not converted to T_4 (T_4 is converted peripherally to T_3), and levothyroxine is the treatment of choice for hypothyroidism, making choices A, B, and C incorrect. Once-daily dosing of liothyronine produces high-peak (and low-trough) levels of the drug in the serum, contributing to side effects associated with signs and symptoms of hyperthyroidism. Therefore, choice D is correct.

12. **C.** An individual patient is recommended to continue to use the same brand or generic version of levothyroxine as T_4 is a narrow therapeutic index drug. While the bioavailability of different brand and generic preparations is considered bioequivalent (the FDA considers a range of 80%-125% of *C*max, *T*max, and AUC equivalent), there may be enough differences to affect subsequent TSH levels. This patient would typically be dosed to maintain a low TSH level (eg, 0.1-1.0 mIU/L) in order to decrease the likelihood of recurrence of her papillary thyroid cancer. If this patient were switched to a T_4 product with less bioavailability, her TSH level would rise, increasing the risk of thyroid cancer recurrence. If this patient is switched to a T_4 product with greater bioavailability, this would likely result in symptoms of over-replacement (hyperthyroidism). While choices A, B, and C are all true statements, choice C is the best answer to the question. Often such patients will be prescribed a branded T_4 preparation as it is easier to ensure the use of the same T_4 preparation. However, consistently using the same generic T_4 preparation is appropriate; thus, choice D is incorrect.

13. **C.** Susan has primary HoTR; hence, an elevated TSH level indicates under-replacement of therapy (not over-replacement—choice A). The current low TT_4 and TT_3 levels (choice B) are not reflective of her final thyroid hormone levels at steady-state. Susan has received 5 weeks of T_4 replacement therapy but has received only 2 weeks of therapy at the present dose of 100 mcg daily. Steady state is reached in 4 to 5 half- lives and the half-life of T_4 is approximately 1 week. Re-equilibration of TSH based on the steady-state levels of FT_4 and TT_3 levels will take an additional 1 to 2 weeks; therefore, Susan should make no change in her current T_4 dose and have FT_4 and THS levels checked in another 4 to 5 weeks.

14. **B.** Thyroid storm is a life-threatening medical emergency characterized by decompensated thyrotoxicosis, high fever, tachycardia, tachypnea, dehydration, delirium, coma, nausea, vomiting, and diarrhea. Even with aggressive treatment, the mortality rate is approximately 20%. Prompt initiation of therapy aimed at the suppression of thyroid hormone formation and secretion, antiadrenergic therapy, administration of corticosteroids, and treatment of associated complications or coexisting factors that may have precipitated the storm is indicated (see Table 96-7). While all of the above medications are typically indicated for treatment, iodide (SSKI and Lugol's solution) should be administered after thioamide is to inhibit iodide utilization by the overactive gland. If iodide is administered first, it could theoretically provide a substrate to produce even higher levels of thyroid hormone.

15. **D.** Myxedema coma is an example of decompensated hypothyroidism and includes hypothermia, advanced stages of hypothyroid symptoms, and altered sensorium ranging from delirium to coma. Mortality rates of 60% to 70% necessitate immediate and aggressive therapy. Traditionally, the initial treatment has been IV bolus levothyroxine 300 to 500 mcg. However, as deiodinase activity is markedly reduced, impairing T_4 to T_3 conversion, initial treatm ent with intravenous T_3, or a combination of both hormones has also been advocated. Glucocorticoid therapy with IV hydrocortisone 100 mg every 8 hours should be given until coexisting adrenal suppression is ruled out. All therapies must be administered parenterally as cessation of gastrointestinal peristalsis occurs, preventing the absorption of orally administered medications. β-Blockers are typically indicated in thyroid storm but are contraindicated in myxedema coma.

Chapter 97: Adrenal Gland Disorders

Steven M. Smith; Christopher R Piszczatoski; John G. Gums

KEY CONCEPTS

KEY CONCEPTS

① Glucocorticoid secretion from the adrenal cortex is stimulated by adrenocorticotropic hormone (ACTH) or corticotropin that is released from the anterior pituitary in response to the hypothalamic-mediated release of corticotropin-releasing hormone (CRH).

② To ensure the proper treatment of Cushing syndrome requires diagnostic procedures to (1) establish the presence of hypercortisolism and (2) discover the underlying etiology of the disease.

③ The rationale for treating Cushing syndrome is to reduce the morbidity and mortality resulting from disorders such as diabetes mellitus, cardiovascular disease, and electrolyte abnormalities.

④ The treatment of choice for both ACTH-dependent and ACTH-independent Cushing syndrome is surgery. Pharmacologic agents are reserved for adjunctive therapy, refractory cases, or inoperable disease.

⑤ Pharmacologic agents that may be used to manage the patient with Cushing syndrome include steroidogenesis inhibitors, adrenolytic agents, neuromodulators of ACTH release, and glucocorticoid-receptor blocking agents.

⑥ Spironolactone, a competitive aldosterone-receptor antagonist, is the drug of choice in bilateral adrenal hyperplasia (BAH)–dependent hyperaldosteronism.

⑦ Addison disease (primary adrenal insufficiency) is a state of deficiency in cortisol, aldosterone, and various androgens due to the loss of function in all regions of the adrenal cortex.

⑧ Secondary adrenal insufficiency usually results from exogenous steroid use, leading to hypothalamic–pituitary–adrenal (HPA)–axis suppression followed by a decrease in ACTH release, and low levels of androgens and cortisol.

⑨ Virilism results from the excessive secretion of androgens from the adrenal gland and often manifests as hirsutism in females.

INTRODUCTION

The adrenals are small endocrine glands located atop each kidney that produce several hormones that regulate blood pressure, metabolism, immune response, stress response, and other bodily functions. Under- or over-production of these hormones cause a constellation of symptoms and most commonly result in Cushing Syndrome (hypercortisolism), Addison's disease (adrenal insufficiency), or hyperaldosteronism. Adrenal disorders affecting the hormone cortisol are rare, typically effecting fewer than 1 person in a thousand. On the other hand, aldosterone-related disorders, particularly hyperaldosteronism, are relatively common. Left untreated, complications from these disorders can include organ damage, physical manifestations, electrolyte abnormalities, cardiovascular crises, and even death. Thus, prompt identification and treatment is critical. Screening and management of these conditions lower the risk of complication, increase life expectancy, and improve quality of life for those affected.[1]

PHYSIOLOGY, ANATOMY, AND BIOCHEMISTRY

The adrenal glands are located on the upper poles of each kidney (Fig. 97-1). On average, each adrenal gland weighs 4 g and is 2 to 3 cm in width and 4 to 6 cm in length. The gland is fed by small arteries from the abdominal aorta and renal and phrenic arteries. Drainage of the adrenal gland occurs via the renal vein on the left and the inferior vena cava on the right.

The adrenal medulla comprises 10% of the total gland and is responsible for the secretion of catecholamines. The adrenal cortex accounts for the remaining 90% and is responsible for the secretion of three types of hormones (Fig. 97-2) from three separate zones.

FIGURE 97-2

Hormone synthetic pathways in relation to the zones of the adrenal cortex.

The zona glomerulosa accounts for 15% of the total adrenal cortex and is responsible for mineralocorticoid production, of which aldosterone is the principal end product. Aldosterone maintains electrolyte and volume homeostasis by altering potassium and magnesium secretion and renal tubular sodium reabsorption. The zona fasciculata, the middle zone, makes up 60% of the cortex, is high in cholesterol, and is responsible for basal and stimulated glucocorticoid production. Glucocorticoids, mainly cortisol, are responsible for the regulation of fat, carbohydrate, and protein metabolism. The zona reticularis occupies 25% of the adrenal cortex and is responsible for adrenal androgen production. The androgens, testosterone, and estradiol are the major end products and influence the reproductive system in addition to modulating primary and secondary sex characteristics.

Hormone Production and Metabolism

Adrenal steroid hormone synthesis begins with the conversion of cholesterol to pregnenolone by cytochrome P450 (CYP) enzymatic side-chain cleavage (Fig. 97-2). Following this rate-limiting step, pregnenolone is converted to various 19- and 21-carbon steroids, depending on the enzymatic capabilities within each zone of the cortex. Androgenic properties predominate in the 19-carbon steroids, whereas mineralocorticoid and glucocorticoid properties manifest in the 21-carbon steroids.

Aldosterone production is initiated by the 21-hydroxylation of progesterone to form deoxycorticosterone. Subsequently, aldosterone synthase converts deoxycorticosterone to aldosterone through the intermediary, corticosterone. The zona glomerulosa preferentially produces aldosterone for three main reasons. First, the zona glomerulosa lacks 17*α*-hydroxylase activity and therefore can only convert pregnenolone to progesterone. Second, in contrast to the other zones, cells in the zona glomerulosa possess aldosterone synthase activity, which catalyzes the terminal steps in aldosterone synthesis. Lastly, cells of the zona glomerulosa display a greater number of angiotensin II receptors than cells of the other zones. The binding of angiotensin II to these receptors provides the stimulus for initiating the aldosterone biosynthesis cascade. Thus, aldosterone synthesis is a unique feature of the zona glomerulosa, explaining why aldosterone is not affected during disease processes limited to the zona fasciculata or reticularis.

Cortisol is produced from pregnenolone via four successive hydroxylations. These hydroxylations occur primarily in the zona fasciculata, although the zona reticularis is also capable of producing glucocorticoids.

Androgens, produced primarily in the zona reticularis and less commonly in the zona fasciculata, have a 19-carbon structure and serve as precursors to more potent analogs produced in the periphery. The adrenal gland can synthesize estradiol and estrone from testosterone and androstenedione, respectively; however, the quantities synthesized by the adrenal gland are extremely small. The rates of production for the various steroids produced by the adrenal gland are listed in Table 97-1.

TABLE 97-1

Rates of Adrenal Production and Plasma Concentrations of Various Steroids

Steroid	24-hour Secretion (mg)	Plasma Concentration
Aldosterone	0.15 (0.42 μmol)	2-9 ng/dL (55-250 pmol/L; supine, normal-sodium diet)
Androstenedione	2.2-2.5 (7.7-8.7 μmol)	50-250 ng/dL (1.7-8.7 nmol/L)
Corticosterone	1-4 (3-12 μmol)	2.4 ± 1.5 ng/dL (69 ± 43 nmol/L; female) 4.2 ± 2.2 ng/dL (121 ± 64 nmol/L; male)
Cortisol 11-Deoxycorticosterone	8-25 (22-69 μmol) 0.60 (1.8 μmol)	0-25 μg/dL (0-690 nmol/L) 2-19 ng/dL (60-575 pmol/L)
11-Deoxycortisol	0.40 (1.2 μmol)	12-158 ng/dL (350-4560 pmol/L)
Progesterone	0	<20 ng/dL (0.6 nmol/L; female)[a] 300-2,000 ng/dL (9.5-64 nmol/L; female)[b] <20-140 ng/dL (0.6-4.5 nmol/L; male)
Testosterone (total)	0.23 (0.8 μmol; female)	6-86 ng/dL (0.2-3.0 nmol/L; female) 270-1,070 ng/dL (9.4-37 nmol/L; male)

Glucocorticoid metabolism occurs in the liver and is responsible for converting inactive steroids to active metabolites, as well as modifying active steroids to less active or inactive metabolites. Most pharmaceutical steroid products are active; however, in the case of prednisone and cortisone, metabolism is necessary for conversion to the active prednisolone and cortisol, respectively.

Following metabolic conversion, glomerular filtration is primarily responsible for eliminating endogenously produced glucocorticoids. The half-life of cortisol is 70 to 120 minutes, whereas aldosterone exhibits extremely high intrinsic clearance and a half-life of only 15 minutes.

Metabolism and conversion of the various steroids can be altered by a variety of disease states and medicinal compounds. Drugs known to enhance steroid clearance include phenytoin, phenobarbital, rifampin, and mitotane. Likewise, diseases such as hyperthyroidism and renal disease can enhance steroid clearance. In contrast, drugs such as estrogens and estrogen-containing oral contraceptives reduce steroid clearance. Similarly, liver disease, age, pregnancy, hypothyroidism, anorexia nervosa, protein-calorie malnutrition, and renal disease are associated with reduced steroid clearance.

Plasma glucocorticoids are bound to one of three plasma proteins in varying degrees. Corticosteroid-binding globulin (CBG), albumin, and α_1-glycoprotein are capable of binding glucocorticoids, with CBG being the principal binding protein. Steroid binding serves as a reservoir for steroids in their inactive state and more than 95% of cortisol is normally bound. Binding to plasma proteins prevents glucocorticoid activity at receptor-activating sites. Therefore, a final but important variable in the altered plasma concentration of free (active) steroids is the concentration of plasma proteins.

Regulation of Hormone Secretion

① Glucocorticoid secretion is regulated by the pituitary hormone, adrenocorticotropic hormone (ACTH [also known as corticotropin]). Under normal conditions, ACTH is released from the anterior pituitary in response to corticotropin-releasing hormone (CRH), which is secreted by the median eminence of the hypothalamus (Fig. 97-3). Vasopressin and oxytocin have weak ACTH-releasing activity through binding to the inferior V_3 receptor. CRH, in combination with vasopressin and oxytocin, stimulates greater ACTH secretion than each hormone individually.

FIGURE 97-3

Negative feedback system involved in the regulation of cortisol secretion under normal conditions.

Additionally, histochemical studies have demonstrated that certain neurotransmitters, such as serotonin and norepinephrine, can stimulate the production of CRH and ACTH. After release, ACTH stimulates the adrenal gland to release cortisol and, to a lesser extent, aldosterone and androgens. The rising cortisol concentration inhibits the secretion of CRH and ACTH through a negative feedback mechanism. In addition, leptin, an adipocyte hormone, has an inhibitory effect on hypothalamic–pituitary–adrenal (HPA) activity.

Adrenal androgens are regulated in a similar fashion to cortisol. When plasma androgen reaches sufficient concentrations, production is terminated via a negative feedback loop. Androgen release is increased during puberty and in women with hirsutism. Adrenal androgen release decreases with age and in fasting states, including anorexia nervosa.

In contrast to cortisol and adrenal androgens, the regulation of aldosterone secretion is considerably more complex. The renin-angiotensin system regulates aldosterone secretion through both intrarenal and extrarenal mechanisms. Renin production and subsequent aldosterone secretion are stimulated by blood pressure-lowering (due to volume depletion), erect posture, salt depletion, β-adrenergic stimulation, and CNS excitation (see

Chapter 30, “Hypertension”). Renin production is inhibited by salt loading, angiotensin II, vasopressin, potassium, calcium, blood pressure increases, and a variety of drugs. The renin-mediated production of angiotensin II is the initial stimulus for aldosterone synthesis. Additionally, angiotensin II can be acted on by aminopeptidase and converted to angiotensin III. Both angiotensin II and III are capable of stimulating the zona glomerulosa to secrete aldosterone. Following aldosterone secretion, increases in renal sodium, water retention, and blood pressure occur thereby turning off the stimulus for renin release.

HYPERFUNCTION OF THE ADRENAL GLAND

Adrenal disorders can be categorized as hyperfunction or hypofunction of the adrenal gland. Hyperfunction of the adrenal gland generally involves excess production of adrenal hormones, most notably cortisol, resulting in Cushing syndrome, or aldosterone, resulting in hyperaldosteronism.

Cushing Syndrome

In 1932, Cushing first described a syndrome of pituitary basophilism that attracted national attention. These patients had unexplained central obesity, cutaneous striae, osteoporosis, weakness, hypertension, diabetes mellitus, and congestion. Cushing believed the disease was of a pituitary origin. Ten years later, Albright focused his attention on the “sugar hormone,” which he believed originated from the adrenal cortex.[2] It was not until the development of a method to measure urinary steroids did it become clear that elevated steroids in patients with Cushing syndrome were the result of excess plasma cortisol (hypercortisolism).

Cushing syndrome results from the effects of supraphysiologic concentrations of glucocorticoids originating either from the exogenous administration or, less commonly, endogenous overproduction by the adrenal glands. Excess glucocorticoids are produced in response to the overproduction of ACTH (ACTH-dependent) or by abnormal adrenocortical tissues (ACTH-independent). ACTH-dependent Cushing syndrome (≈80% of all Cushing syndrome cases) usually originates from an overproduction of ACTH by the pituitary gland. Excessive ACTH chronically stimulates the adrenal glands causing bilateral adrenal hyperplasia (BAH). Approximately 85% of these cases are caused by pituitary adenomas (Cushing disease). Ectopic ACTH-secreting tumors and non-neoplastic corticotropin hypersecretion, possibly secondary to excess CRH production, account for the remainder of ACTH-dependent causes.[3] Ectopic ACTH syndrome refers to excessive ACTH production resulting from an endocrine or nonendocrine tumor, usually of the pancreas, thyroid, or lung. Small-cell carcinoma of the lung will lead to ectopic ACTH secretion in 0.5% to 2% of cases, whereas bronchial carcinoid tumors are usually the most common.[4] Distinguishing between the various etiologies requires a careful history and laboratory work (Table 97-2).

TABLE 97-2

Various Etiologies of Cushing Syndrome and Their Respective Differences

	Pituitary-Dependent	Ectopic ACTH Syndrome	Adrenal Adenoma	Adrenal Carcinoma
Course	Slow	Rapid	Slow	Rapid
Symptoms	Mild to moderate	Atypical	Mild to moderate	Severe
Dominant sex/age	Female/male	Male	None noted	Children
Virilization	+	+	+	+++
Abdominal mass	0	0	0	++
Plasma ACTH concentration	Slightly elevated	High	Low	Low
Dexamethasone suppression test	≥50% suppression	No suppression	No suppression	No suppression
Iodocholesterol scan	Bilateral uptake	Bilateral uptake	Unilateral	None

The remaining 20% of Cushing syndrome cases are ACTH-independent and divided almost equally between adrenal adenomas and adrenal carcinomas. In rare cases, macronodular hyperplasia, primary pigmented nodular adrenal disease, or McCune–Albright syndrome is the culprit.[3,5] The majority of adrenal cortex tumors are benign adenomas. Adrenal carcinoma is found more often in children than in adults with Cushing syndrome.

Patients with Cushing syndrome commonly present (>90% of patients) with central obesity and facial rounding. Approximately 50% of patients exhibit some peripheral obesity and fat accumulation. Fat accumulation in the dorsocervical area (buffalo hump) is often associated with weight gain, whereas increased supraclavicular fat pads are more specific for Cushing syndrome. Striae are usually present along the lower abdomen and have a red to purple color. Traditionally, complications caused by high blood pressure have been major contributors to the morbidity and mortality of Cushing syndrome. Hypertension is diagnosed in 75% to 85% of patients, with diastolic blood pressures greater than 119 mm Hg noted in over 20% of patients.[6] Glucose intolerance is present in 60% of patients. Thus, many patients meet diagnostic criteria for the metabolic syndrome and have a corresponding increased risk of coronary heart disease (CHD) and stroke. Screening for Cushing syndrome in this population and in patients with uncontrolled diabetes mellitus has been suggested,[7,8] particularly when these conditions surface at an unusually early age.[9] However, screening all patients with type 2 diabetes is likely not cost-effective.[10]

CLINICAL PRESENTATION: Cushing Syndrome

General

- The most common findings, which are present in 90% of patients, are central obesity and facial rounding.

Symptoms

- A majority of patients complain of myopathies and muscular weakness.

Signs

- Peripheral obesity and fat accumulation are found in 50% of patients.
- Facial plethora is caused by underlying atrophy of the skin and connective tissue.
- Patients often are described as having moon faces with a buffalo hump.
- Hypertension is seen in 75% to 85% of patients.
- Psychiatric changes can occur in as many as 55% of patients.
- Approximately 50% to 60% of patients will develop Cushing syndrome–induced osteoporosis. Of these, 40% will present with back pain and 20% will have compression fractures of the spine.
- Gonadal dysfunction is common with amenorrhea seen in up to 75% of females.
- Hirsutism is present in 80% of females.

Laboratory Tests

- A midnight plasma cortisol, late-night salivary cortisol, 24-hour urinary free cortisol (UFC), and/or low-dose dexamethasone suppression test (DST) will establish the presence of hypercortisolism.

Other Diagnostic Tests

- The plasma ACTH test, metyrapone stimulation test, CRH stimulation test, or inferior petrosal sinus sampling (IPSS) will help determine the etiology.

Iatrogenic (exogenous) causes of the Cushing syndrome is the most common etiology. Therefore, all patients exhibiting hypercortisolism should undergo a comprehensive history and evaluation assessing medication use before laboratory testing is performed to identify endogenous sources. Iatrogenic Cushing syndrome can occur from the administration of oral, inhaled, intranasal, intra-articular, and topical glucocorticoids, as well as progestins such as medroxyprogesterone acetate and megestrol acetate.[11] Disease severity correlates with exogenous glucocorticoid potency, dose, frequency, route, and treatment duration. Moreover, patients taking CYP3A4 inhibitors concurrently with a glucocorticoid can be at higher risk of developing iatrogenic Cushing syndrome.[12,13] If exogenous glucocorticoids are being taken, the plasma cortisol concentration can increase, while the corticosterone concentration remains low.[14]

In the absence of any known exogenous causes, the clinician will need to differentiate the syndrome from other causes, such as pseudo-Cushing syndrome, that mimic true Cushing syndrome. Patients with obesity, chronic alcoholism, depression, and acute illness of any type can present with certain features of Cushing syndrome. For example, patients who have major depressive disorder may have urinary steroid abnormalities seen in Cushing syndrome, but do not have the cushingoid appearance. In chronic alcoholism, steroid laboratory panels generally return to baseline after ceasing alcohol intake. And obese patients often will have normal cortisol concentrations for both serum and urinary screening tests. Thus, identifying true cases of Cushing syndrome requires a comprehensive history in combination with laboratory and possibly imaging assessment.

② The diagnosis of Cushing syndrome involves two steps: (a) establishing the presence of hypercortisolism, which is relatively easy, and (b) determining the etiology, which can be challenging (Fig. 97-4).[5,8,15] The presence of hypercortisolism can be established via one or more of the following tests: 24-hour UFC, midnight plasma cortisol, late-night salivary cortisol, or the low-dose DST (using 1 mg dexamethasone for the overnight test or 0.5 mg/6 hr for the classic 2-day study). However, because these tests cannot determine the etiology of Cushing syndrome, other tests and procedures must be subsequently employed. Such tests can include any of the following: plasma ACTH via immunoradiometric assay (IRMA) or radioimmunoassay (RIA); adrenal vein catheterization; metyrapone stimulation test; adrenal, chest, or abdominal computed tomography (CT); CRH stimulation test; inferior petrosal sinus sampling (IPSS); jugular venous sampling (JVS); cavernous sinus sampling; and pituitary magnetic resonance imaging (MRI). High-dose DST has been used in the past but is no longer recommended due to its poor specificity and limited diagnostic value. Other possible tests and procedures include insulin-induced hypoglycemia, somatostatin receptor scintigraphy, the desmopressin stimulation test, the naloxone CRH stimulation test, the loperamide test, the hexarelin stimulation test, and radionuclide imaging.[5,6,8,15–20] Table 97-3 summarizes the findings from some of the tests used to diagnose Cushing syndrome.

TABLE 97-3

Summary of Tests Used to Diagnose Cushing Syndrome

Test	Normal	Hyperplasia	Adenoma	Carcinoma
Plasma				
Cortisol (μg/dL or nmol/L, in brackets; for am/pm)	5-25/5-15 (140-690/140-415)	↑/↑↑	↑↑/↑↑	↑↑↑/↑↑↑
After low-dose DST	↓	↔	↔	↔
After high-dose DST	↓	↓/↔	↔	↔
ACTH (pg/mL or pmol/L, in brackets)	6-76 (1.3-17)	↑↑	↓	↓
Urine				
Cortisol (μg/24 hours or nmol/day, in brackets)	20-90 (55-250)	↑↑	↑↑	↑↑↑
Saliva				
Cortisol (μg/dL or nmol/L), PM)	Assay-dependent	↑↑	↑↑	↑↑↑

Data from Kratz A, Ferraro M, Sluss PM, Lewandrowski KB. Laboratory reference values. N Engl J Med. 2004;351(15):1548-1563.

Elevated UFC concentrations are highly suggestive of Cushing syndrome, especially values fourfold greater than the upper limit of normal.[3,17] In contrast to plasma measurements of cortisol, UFC measures only unbound cortisol. Consequently, the UFC test is unaffected by conditions and medications that alter CBG levels. Normal reference values for UFC are 10 to 60 μg per 24-hour period (30-170 nmol/day). A two- to threefold increase in urine cortisol is not uncommon in the patient with hyperfunction of the adrenal gland. Starvation, hydration from water loading (≥5 L/day), alcoholism, and acute stress are all capable of elevating urine cortisol concentrations. Likewise, elevated UFC results can occur during therapy with carbamazepine, fenofibrate, and topical steroids depending on the type of UFC test. Conversely, renal impairment (creatinine clearance [CrCl] of <60 mL/min [1.0 mL/s]) can falsely lower UFC concentrations. Because other pathologic conditions can increase the amount of free cortisol, additional tests may be warranted to confirm the diagnosis, or the diagnostic evaluation should be repeated when the acute stress has resolved. Of all urinary measures, UFC is the most useful assessment for patients with suspected Cushing syndrome.[8,17,19]

In healthy individuals, cortisol release follows a circadian rhythm whereby serum cortisol concentration peaks around 8:00 am and thereafter declines by 60% to 80%, reaching a nadir between 1:00 and 3:00 am. This rhythm is lost in the patient with Cushing syndrome. Although many patients with

Cushing syndrome will have serum cortisol values in the high normal range if the serum is assayed in the morning, only 3.4% will have normal values if measured late at night.[14] Thus, a midnight serum cortisol greater than 7.5 µg/dL (210 nmol/L; >1.8 µg/dL [50 nmol/L]if the patient is sleeping) is a highly sensitive assay for Cushing syndrome. However, this test is cumbersome and rarely recommended because it requires that patients be admitted for more than 48 hours to avoid false-positive responses secondary to the stress of hospitalization. An alternative assay is the measurement of late-night salivary cortisol. Salivary cortisol is highly correlated with free serum cortisol and independent of salivary flow rates. Moreover, salivary cortisol concentration reflects changes in serum cortisol within minutes. Salivary cortisol can be considered an acceptable alternative to UFC because of its convenience, stability (1 week), accuracy, and reproducibility. Unfortunately, normal reference ranges are assay-dependent, and cutoff points vary among institutions.[21,22]

In the overnight DST, 1 mg of dexamethasone is administered at 11:00 pm. The following morning at 8:00 am fasting plasma cortisol is obtained for analysis. This supraphysiologic dose of dexamethasone suppresses ACTH stimulation and cortisol production in healthy individuals. In contrast, the negative feedback loop is ineffective in patients with Cushing syndrome who generally exhibit a morning cortisol concentration above 5 µg/dL (140 nmol/L). Some patients with Cushing syndrome administered the overnight DST can slightly suppress cortisol and using a 1.8 µg/dL (50 nmol/L) threshold can increase sensitivity, but with reduced specificity.[23] Therefore, the overnight DST is useful only as a screening tool for Cushing syndrome. Drugs that induce or inhibit CYP3A4 metabolism can significantly alter dexamethasone concentration, increasing the likelihood of false-positive and false-negative DSTs. Concurrent measurements of dexamethasone concentration with cortisol may improve the accuracy of testing for patients on CYP3A4-modifying drugs, although dexamethasone assays are not widely available. Also noteworthy, pregnancy and estrogen use (including oral contraceptives) increase CBG levels and frequently elicit false-positive results.[17] Consequently, UFC testing is preferred over DST in these patient populations.

The first test used to determine the etiology of Cushing syndrome is the plasma ACTH test. Plasma ACTH concentrations can be measured via RIA or IRMA.[16] In ACTH-dependent Cushing syndrome, ACTH can be normal or elevated. Very high levels of ACTH favor ectopic production. In contrast, ACTH values generally are low (<5 pg/mL [1.1 pmol/L]) in ACTH-independent (adrenal) Cushing syndrome. Furthermore, ACTH levels can appear artificially low in some ectopic ACTH-producing tumors because ACTH can be secreted as an active prohormone that is not detected by the assay.

IPSS offers the highest sensitivity and specificity of any test in differentiating the etiology of Cushing syndrome. This technique requires catheterization of both petrosal sinuses with serial measurements of ACTH in each sinus and a peripheral vein after administration of CRH. A central-to-peripheral ACTH gradient is diagnostic for Cushing disease, whereas no gradient indicates ectopic ACTH production. Complications, such as venous thromboembolism, brain stem vascular damage, high cost, and technical expertise, can limit the use of this test.[16] JVS uses the same concept as IPSS, is less invasive, and produces fewer complications; however, sensitivity is compromised.

Abnormal adrenal anatomy is effectively identified using high-resolution CT scanning and MRI.[24] Nodules as small as 1 to 1.5 cm on the adrenal cortex are easily identified by CT. With the use of thin-section scanning, nodules as small as 3 to 5 mm can be visualized.[25] Importantly, adrenal incidentalomas (masses observed incidentally on imaging) are prevalent in 5% to 10% of the general population. These masses may be functional (secreting), requiring intervention, or nonfunctional (nonsecreting), requiring only periodic observation. For this reason, abnormal imaging results alone are insufficient to conclusively diagnose adrenal disease. Nonadrenal imaging studies may be useful for identifying ectopic sources of ACTH secretion in patients for whom IPSS has ruled out Cushing disease.

③ If left untreated, Cushing syndrome is associated with high morbidity and mortality due to hypertension, diabetes mellitus, cardiovascular disease, and electrolyte abnormalities. On average, patients with Cushing syndrome live only 4 to 5 years following initial diagnosis. The desired outcomes of treatment are to limit such detrimental outcomes and return the patient to a normal functional state by removing the source of hypercortisolism while minimizing pituitary or adrenal deficiencies.

④ The treatment of choice for both ACTH-dependent and ACTH-independent Cushing syndrome is surgical resection of any offending tumors.[3,15] Pharmacologic treatment options which target the etiology of the disease are generally reserved as second-line treatment for those patients who are not surgical candidates (Table 97-4).[3,26–29] Pharmacotherapy may also be used preoperatively or as adjunctive therapy in the postoperative period awaiting a response. Rarely, pharmacotherapy is used as a palliative treatment when surgery is not indicated.

TABLE 97-4

Possible Treatment Options in Cushing Syndrome Based on Etiology

	Treatment	
Etiology	Non-pharmacologic	Pharmacologic
Ectopic ACTH syndrome	Surgery, chemotherapy, irradiation	Metyrapone Ketoconazole
Pituitary-dependent	Surgery, irradiation	Mitotane Metyrapone Mifepristone Cabergoline Pasireotide
Adrenal adenoma	Surgery, postoperative replacement	Ketoconazole
Adrenal carcinoma	Surgery	Mitotane

Non-Pharmacologic Therapy

Pituitary Adenoma

The treatment of choice for Cushing disease is transsphenoidal resection of the pituitary tumor.[3,15,29–31] The advantages of this procedure include preservation of pituitary function, low complication rate, and high clinical improvement rate. The overall cure rate of histologically proven microadenomas (tumor diameter <10 mm) approaches 90%, whereas remission rates for macroadenomas (tumor diameter ≥10 mm) generally do not exceed 65%.

For persistent disease following transsphenoidal surgery or when tumor-specific surgery is not possible, several second-line treatment options are available and should be tailored toward the individual patient.[29] In the case of persistent disease following transsphenoidal surgery, repeat surgery may be performed, particularly in patients with evidence of incomplete resection or pituitary lesion on imaging.[29] Although overall remission rates are lower with subsequent procedures, remission can be achieved rapidly when compared to alternative second-line treatments.[29] Alternatively, radiotherapy may be preferred for tumors invading the dura or cavernous sinus because these tumors respond poorly to surgical intervention.[32] Radiotherapy provides clinical improvement in approximately 50% of patients within 3 to 5 years, but increases the risk for pituitary-dependent hormone deficiencies (hypopituitarism).

Adrenal Adenoma

Laparoscopic adrenalectomy is often preferred in patients with unilateral adrenal adenomas for whom transsphenoidal surgery and pituitary radiotherapy have failed or cannot be used.[3,15,30] Bilateral adrenalectomy rapidly reverses hypercortisolism. However, patients can develop Nelson syndrome, an aggressive pituitary tumor that secretes high quantities of ACTH, which causes hyperpigmentation. Because Nelson syndrome occurs in as many as 30% of bilateral adrenalectomy cases, patients should undergo regular MRI scans and ACTH level assessments. Additionally, these patients require lifelong glucocorticoid and mineralocorticoid supplementation.

Surgical resection of benign adrenal adenoma is associated with relatively few side effects and a high cure rate (95%). The contralateral gland in the patient with adrenal adenoma is usually atrophic; therefore, steroid replacement is needed both perioperatively and postoperatively. Table 97-5 outlines an approach to steroid replacement for three separate routes of hydrocortisone. Therapy should be continued for 6 to 12 months following surgery. Before replacement therapy is discontinued, recovery of the adrenal axis can be assessed by measuring the morning (8:00 am) cortisol concentration. The cortisol concentration should exceed 20 μg/dL (550 nmol/L) before discontinuing exogenous steroids.[11]

TABLE 97-5

Alternative Steroid Replacement Regimens in the Adrenal Adenoma Patient

	Hydrocortisone Dose (mg)		
Time	IV	IM	po
Operation day	300	50 before surgery and 50 after surgery	
Postoperative day 1	200	50 every 12 hours	
Postoperative day 2	150	50 every 12 hours	
Postoperative day 3	100	50 every 12 hours	
Postoperative day 4		50 every 12 hours	25 every 6 hours
Postoperative day 5		25 every 12 hours	25 every 6 hours[a]
Postoperative day 7			25 every 6 hours
Postoperative days 8-10			25 every 8 hours
Postoperative days 11-20			25 every 12 hours

po, orally.

[a] Add fludrocortisone 0.05-2 mg orally once daily starting on postoperative day 5. Adjust dose based on blood pressure, body weight, and serum electrolytes.

Adrenal Carcinoma

Unlike the benign adenoma patient, those with adrenal carcinoma generally have an unfavorable outcome with surgical resection.[15] Often the complete tumor cannot be excised, leaving the patient with some degree of symptoms and extra-adrenal involvement. Radiotherapy can be used if metastases are discovered. In a patient with adrenal carcinoma who is not a surgical candidate, the focus of treatment is on palliative pharmacologic intervention.

Mitotane may be used in inoperable functional and nonfunctional adrenal carcinoma or as adjuvant therapy in surgical patients with a high risk of relapse and may prolong survival by 2 to 3 years.[33] However, mitotane induces tumor regression in fewer than 20% of patients.[34] Metyrapone and ketoconazole can be given as adjunctive treatment to attempt control of steroid hypersecretion. 5-Fluorouracil also has been used in combination therapy.

Ectopic Adrenocorticotropic Hormone Syndrome

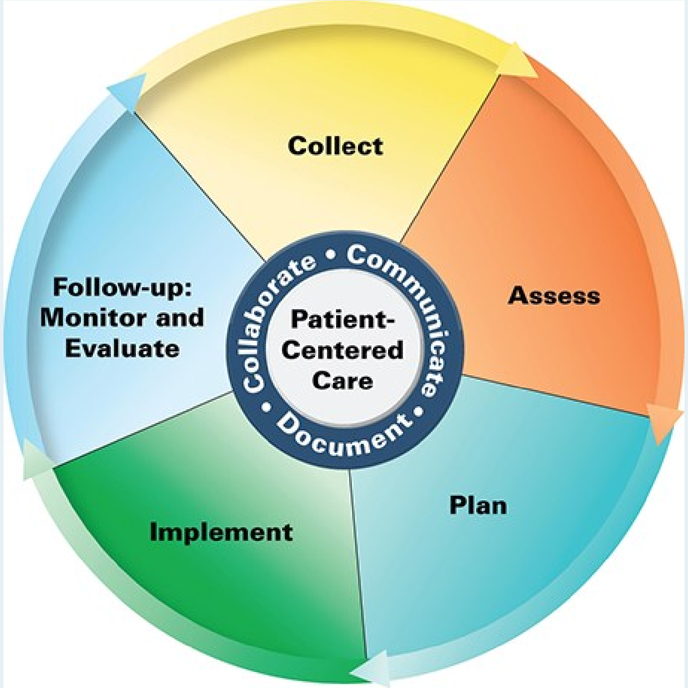
In ectopic ACTH syndrome, ACTH-secreting tumors may exist in a variety of sites, including thymic, pulmonary, appendiceal, pancreatic, and thyroid tissues. Locating these sites is often difficult, but essential for determining an appropriate treatment strategy. Surgical resection is the most effective treatment option for these patients, but only approximately 10% to 30% of patients are cured following surgery due to high rates of metastatic disease or occult tumors. The remaining 70% to 90% receive postoperative medication.

Pharmacologic management with steroidogenesis inhibitors is effective in patients with ectopic ACTH syndrome and may be used as primary treatment in patients with occult or metastatic ectopic ACTH syndrome.[29] Mitotane has been used in this setting; however, its side-effect profile generally limits its use. Mifepristone and somatostatin analogs also have been reported to reduce the clinical signs of ectopic ACTH syndrome.[35]

Additional tumor-directed therapy can include systemic chemotherapy, interferon α, chemoembolization, radiofrequency ablation, and radiation therapy.[32] If all else fails, bilateral adrenalectomy can prevent the downstream effects (eg, steroidogenesis) of high levels of tumor ACTH secretion.

PATIENT CARE PROCESS

Patient Care Process for Cushing Syndrome



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use)
- Iatrogenic causes of Cushing syndrome: current medications including corticosteroids (all routes, past and present), medroxyprogesterone acetate, megestrol acetate, gamma-hydroxybutyic acid, CYP3A4 inhibitors, and inducers
- Objective data
    - Blood pressure, heart rate, body mass index

  - Test for hypercortisolism: 24-hour UFC, midnight plasma cortisol, late-night salivary cortisol, or low-dose DST
  - Follow-up diagnostic tests to differentiate etiologies (see Fig. 97-4)

Assess

- Presence of Cushing syndrome complications:
  - Metabolic: impaired glucose metabolism, dyslipidemia
  - Cardiovascular: hypertension, vascular damage, thrombosis, hypokalemia
  - Immunologic: bacterial, fungal, and viral infections; rebound autoimmunity Musculoskeletal: osteopenia/osteoporosis, myopathy
  - Neuropsychiatric: depression, anxiety, bipolar disorder, lethargy
  - Reproductive: decreased libido, hypogonadism (men), menstrual irregularity (women)
  - Dermatologic: hirsutism, alopecia, hyperhidrosis
- Physical exam: Peripheral obesity, fat accumulation (Buffalo Hump), rounded face (moon face), striae, ecchymosis, hyperpigmentation, acanthosis nigricans, acne, and thin skin
- Current medications that may contribute to or worsen Cushing syndrome.
- Results of follow-up diagnostic testing for etiology (see Fig. 97-4 and Tables 93-2 and 93-3)
- Ability/willingness to pursue surgical/chemotherapeutic (if indicated) versus medical management

Plan*

- Ensure proper administration of necessary corticosteroid therapy; discontinue unnecessary corticosteroid therapy, with taper if HPA axis integrity is suspect
- Nondrug options for endogenous Cushing syndrome, depending on etiology: surgery, chemotherapy, irradiation, postoperative steroid replacement (see Table 97-4)
- Steroid replacement regimens postoperatively for patients with adrenal adenomas (see Table 97-5)
- Medical management when surgery is not possible or against patient wishes (see Tables 93-6 and 93-7 for specific drugs, dose, route, frequency, adverse effects, and monitoring parameters)
- Patient education (eg, purpose of treatment, dietary and lifestyle modification, invasive procedures, drug-specific information) and specialist referral when appropriate (eg, endocrinologist)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up for monitoring

Follow-up: Monitor and Evaluate

- Clinical response, including resolution of signs/symptoms

- Treatment-emergent adverse effects (eg, adrenal insufficiency [all], medication-specific adverse effects)
- Monitoring parameters including efficacy (eg, UFC) and safety (eg, ECG, liver function, electrolytes, A1c)
- Frequency and timing of follow-up for specific agents (see Table 97-7 and text for agent-specific monitoring)

Collaborate with patient, caregivers, and other healthcare professionals.

Pharmacologic Therapy

⑤ Pharmacotherapy of Cushing syndrome can be divided into four categories based on the anatomic site of action: (1) steroidogenesis inhibitors, (2) adrenolytic agents, (3) neuromodulators of ACTH release, and (4) glucocorticoid-receptor blocking agents.[26,27] Dosing and monitoring parameters can be found in Table 97-6 and Table 97-7, respectively.[3,28,29]

Several factors may limit the ability to personalize pharmacotherapy in patients with Cushing syndrome. First, few rigorous studies have compared the various pharmacologic options used in Cushing syndrome. Apart from the benefits seen with pasireotide in patients with modestly elevated UFC and the use of mifepristone in patients with concomitant hyperglycemia, data are limited in terms of clinical predictors of disease response to these agents. Second, virtually nothing is known of the pharmacogenomic predictors of individual patient response in these disease states. Finally, because most agents are used off-label, scarce data exist on agent-specific pharmacokinetic parameters in this patient population.

TABLE 97-6

Drug Dosing in the Treatment of Cushing Syndrome

Drug	Initial Dose	Usual Range	Special Populations	Comments
Cabergoline	0.5 mg once weekly	0.5-7 mg once weekly		Maximum: 7 mg/week
Etomidate	0.03 mg/kg IV bolus	0.1-0.3 mg/kg/hr infusion		Maximum: 0.3 mg/kg/hr infusion; titrate based on serum cortisol concentration
Ketoconazole	200 mg once or twice a day	200-1,200 mg/day, divided twice a day	Contraindicated in patients with hepatic disease	Maximum: 1,600 mg/day; CYP3A4 substrate and inhibitor (strong)>
Metyrapone	0.5-1 g/day, divided every 4-6 hours	1-2 g/day, divided every 4-6 hours		Maximum: 6 g/day; CYP3A4 inducer
Mifepristone	300 mg once daily, increased by 300 mg/day every 2-4 weeks	600-1,200 mg/day	Do not exceed 600 mg/day in mild-to-moderate hepatic impairment; avoid in severe hepatic impairment. Do not exceed 600 mg/day in renal impairment	Maximum: 1,200 mg/day not to exceed 20 mg/kg/day
Mitotane	0.5-1 g/day, increased by 0.5-1 g/day every 1-4 weeks	1-4 g/day		Maximum: 12 g/day (most patients unable to tolerate >8 g/day). Take with food to decrease GI effects
Osilodrostat	2mg twice daily	2-7 mg twice daily	Moderate hepatic impairment – 1 mg twice daily; Severe hepatic impairment 1 mg once daily in the evening	Comments: Maximum 60 mg/day
Pasireotide	0.6-0.9 mg twice daily	0.3-0.9 mg twice daily	Reduce dose in hepatic impairment	Maximum: 1.8 mg/day

GI, gastrointestinal.

TABLE 97-7

Drug Monitoring in the Treatment of Cushing Syndrome

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Cabergoline	Nausea, dizziness, headache, nasal congestion, constipation, psychiatric symptoms, valvulopathy	Echocardiogram	
Etomidate	Sedation, pain at the injection site, hypotension, myoclonus, nausea, vomiting	Frequent sedation scoring initially, serum potassium, serum cortisol	
Ketoconazole	GI upset, dermatologic reactions; elevated hepatic transaminases, hepatotoxicity	Liver function tests, including ALT/AST, total bilirubin, ALP, prothrombin time, and INR testing	Approximately 10% will experience reversible LFT elevations
Metyrapone	Androgenic effects (hirsutism, acne, etc.), blood pressure and electrolyte abnormalities, nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, allergic rash	Blood pressure, electrolytes	
Mifepristone	Hypokalemia, nausea, fatigue, headache, peripheral edema, dizziness, endometrial hyperplasia	Serum potassium, pregnancy testing, pelvic ultrasound	Abortifacient; rule out pregnancy in women of childbearing potential
Mitotane	GI upset, nausea, diarrhea, lethargy, somnolence, CNS disturbances	UFC and urinary steroid production, serum potassium	GI upset in up to 80%; GI and CNS effects appear to be dose-dependent
Pasireotide	Nausea, diarrhea, cholelithiasis, increased hepatic transaminases, hyperglycemia, sinus bradycardia, QT prolongation	Serum glucose, serum potassium, hemoglobin A1c, liver function tests, UFC, thyroid function, heart rate, ECG	Only available as a subcutaneous injection; expensive

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CNS, central nervous system; FDA, Food and Drug Administration; INR, international normalized ratio; LFT, liver function tests.

With these limitations in mind, drug selection is determined according to the etiology of Cushing syndrome, individual patient factors, drug-drug interactions, and cost. Once the etiology has been correctly identified, patient sex and gender should be considered since some pharmacologic options (steroidogenesis inhibitors in particular) used in Cushing syndrome affect the sex hormones. Specifically, metyrapone is a clear second choice in women due to a high incidence of hirsutism, whereas ketoconazole may be a secondary choice in men due to drug-induced gynecomastia and hypogonadism. During pregnancy, metyrapone is commonly used, while mifepristone must be avoided. Additionally, women desiring pregnancy within the next 5 years should avoid mitotane as this agent is stored in adipose tissue for up to several years following discontinuation. Preexisting medication profiles should also be considered since many of the pharmacologic options can inhibit (eg, ketoconazole) or induce (eg, metyrapone) important CYP isoenzymes such as 3A4.

Ultimately, pharmacotherapy is guided by patient response and several agents may need to be sequentially tried to elicit a substantial response. Combination therapy may be more effective and better tolerated than monotherapy in some patients, but studies involving multi-drug regimens are lacking.

Steroidogenesis Inhibitors

As their name implies, steroidogenesis inhibitors block the production of cortisol. This class includes metyrapone, ketoconazole, etomidate, and osilodrostat. Metyrapone inhibits 11β-hydroxylase, the enzyme responsible for converting 11-deoxycortisol to cortisol. Following administration, a sudden decrease in cortisol concentration occurs within hours and prompts a compensatory rise in plasma ACTH concentrations. As ACTH increases and blockage of cortisol synthesis persists, adrenal steroidogenesis efforts are shunted toward androgen production. Consequently, metyrapone is associated with significant androgenic side effects, including hirsutism and increased acne, making it less ideal for women. In addition, metyrapone blocks aldosterone synthesis and causes the accumulation of aldosterone precursors, which exhibit weak mineralocorticoid activity. Blood pressure and electrolyte perturbations can ensue, depending on the level of circulating 11-deoxycortisol and the degree of aldosterone inhibition. Additional adverse effects, including nausea, vomiting, vertigo, headache, dizziness, abdominal discomfort, and allergic rash, have been reported following administration, but are often signs of overtreatment.[26,27,30]

The imidazole derivative antifungal, ketoconazole, effectively inhibits steroidogenesis via multiple mechanisms when used in large doses. In contrast to the quick onset of metyrapone, the benefits of ketoconazole therapy are achieved only after several weeks of therapy. In addition to lowering serum cortisol levels, ketoconazole exhibits antiandrogenic activity attributable to its inhibition of multiple CYP enzymes as well as 11β-hydroxylase and 17α-hydroxylase.[26] This activity may be beneficial in women with Cushing syndrome but can cause gynecomastia and hypogonadism in men. Sustained therapy with ketoconazole also imparts beneficial effects on serum cholesterol profiles, including lowering total and low-density lipoprotein (LDL) cholesterol levels. Ketoconazole induces a reversible elevation of hepatic transaminases in approximately 10% of patients.[36] However, concerns have been raised over the risk of severe hepatotoxicity associated with ketoconazole use. In July 2013, the US Food and Drug Administration (FDA) significantly changed the labeling of oral ketoconazole, removing various indications for fungal infections and recommending that oral ketoconazole not be used as first-line therapy for fungal infections. Similarly, the European Medicines Agency has recommended the complete removal of oral ketoconazole from European Union markets. These changes were based largely on data in patients with fungal infections, who require lower doses of ketoconazole. However, few data are available on the incidence of severe hepatotoxicity with ketoconazole at the higher doses used in Cushing syndrome. Consequently, monitoring during treatment with ketoconazole should include liver function at baseline, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), total bilirubin, alkaline phosphatase (ALP), prothrombin time, and international normalized ratio (INR) testing, according to FDA recommendations. In addition, weekly monitoring of serum ALT should be continued throughout therapy with ketoconazole. In general, ketoconazole should be avoided in patients with preexisting hepatic disease. Additional common adverse effects include gastrointestinal (GI) discomfort and dermatologic reactions.

Ketoconazole may be used concomitantly with metyrapone to achieve synergistic reductions in cortisol levels. Because these drugs differ in their onset of action, coadministration allows for more complete suppression of cortisol synthesis. Moreover, the antiandrogenic actions of ketoconazole therapy may offset the androgenic potential of metyrapone, thus attenuating a major limitation of metyrapone monotherapy.

The anesthetic etomidate is an imidazole derivative similar to ketoconazole that inhibits 11β-hydroxylase.[26] Inhibition of aldosterone synthase and antiproliferative effects on adrenal cortical cells may also play a role.[37] Etomidate is available only in a parenteral formulation and is therefore limited to patients with acute hypercortisolemia requiring emergency treatment or in preparation for surgery. Low doses of etomidate are often sufficient to suppress cortisol synthesis, thus potentially avoiding some of the adverse effects observed with higher doses used in anesthesia. However, close monitoring is recommended to avoid excess sedation with this agent.[37] Frequent monitoring of serum cortisol is also advised to prevent hypocortisolemia. Replacement corticosteroid doses may be necessary if a complete blockade of cortisol is desired.

Osilodrostat prevents cortisol synthesis via inhibition of 11β-hydroxylase and is indicated for treating patients with Cushing disease who are either not candidates for surgical therapy or in whom symptoms persist after surgery. Osilodrostat is available as an oral tablet administered twice daily, with or without food. Electrolyte imbalances, namely hypokalemia and hypomagnesemia, should be corrected prior to use, and an ECG should be obtained at baseline and again one week after treatment initiation to monitor possible QTc prolongation. Adverse effects are similar to other 11β-hydroxylase inhibitors, including hypocortisolism, QTc prolongation, nausea, and headache.

Adrenolytic Agents

Mitotane is a cytotoxic drug that structurally resembles the insecticide dichlorodiphenyltrichloroethane (DDT). Mitotane inhibits the 11-hydroxylation of 11-desoxycortisol and 11-desoxycorticosterone in the adrenal cortex, resulting in an inhibition of cortisol and corticosterone synthesis. Similar to ketoconazole, mitotane takes weeks to months to exert beneficial effects. Sustained cortisol suppression occurs in most patients (~80%) and may persist following discontinuation of therapy in up to one-third of patients. Because of its cytotoxic nature, mitotane degenerates cells within the zona fasciculata and reticularis, resulting in atrophy of the adrenal cortex. The zona glomerulosa is minimally affected during acute therapy but can be damaged during long-term treatment.[28,29]

Importantly, mitotane can induce significant neurologic and GI side effects and patients should be monitored carefully or hospitalized when initiating therapy. Nausea and diarrhea are common adverse effects that occur at doses greater than 2 g/day and can be avoided by gradually increasing the dose and/or administering the agent with food. Most patients are unable to tolerate doses exceeding 8 g/day. Approximately 80% of patients treated with mitotane develop lethargy and somnolence, and other central nervous system (CNS) adverse drug reactions occur in approximately 40% of patients. Furthermore, significant but reversible hypercholesterolemia and prolongation of bleeding times can result from mitotane use.[26,27] Mitotane increases production of CBG resulting in elevated plasma cortisol measurements; thus, UFC and urinary steroid production should be monitored to assess response to therapy.[26] If necessary, steroid replacement therapy can be given. However, because mitotane also increases extra-adrenal metabolism of exogenously administered corticosteroids (especially hydrocortisone), higher steroid replacement doses may be required. In select patients, supplemental androgen therapy also may be necessary.

Neuromodulatory Agents

Pituitary secretion of ACTH is normally mediated by various neurotransmitters, including serotonin, γ-aminobutyric acid (GABA), acetylcholine, and the catecholamines. Although ACTH-secreting pituitary tumors (Cushing disease) self-regulate ACTH production to some degree, these neurotransmitters are still capable of promoting pituitary ACTH production. Consequently, agents that target these neurotransmitters have been proposed for the treatment of Cushing disease. Such agents include cyproheptadine, ritanserin, ketanserin, bromocriptine, cabergoline, valproic acid, octreotide, lanreotide, pasireotide, rosiglitazone, and tretinoin. However, with the exception of pasireotide, none of these drugs have demonstrated consistent clinical efficacy in the treatment of Cushing disease.

Cyproheptadine, a nonselective serotonin-receptor antagonist and anticholinergic drug, can decrease ACTH secretion in some patients with Cushing disease. However, side effects, including sedation and weight gain, significantly limit the use of this drug. Likewise, selective serotonin type 2-receptor antagonists, including ritanserin and ketanserin, have demonstrated limited efficacy. Owing to their poor efficacy and high relapse rates, these drugs should be avoided except in nonsurgical candidates refractory to more conventional treatments.

Dopamine D_2-receptor agonists, including bromocriptine and cabergoline, initially reduce ACTH secretion in as many as half of all patients with Cushing disease. This action occurs through the activation of inhibitory D_2 receptors that are expressed in approximately 80% of pituitary adenomas.[38] Reductions in ACTH levels are often minor and rarely sustained with long-term bromocriptine therapy. Cabergoline exhibits a higher specificity and affinity for D_2 receptors as well as a prolonged half-life compared with bromocriptine. These differences may explain the greater response rates observed with cabergoline monotherapy; however, a sustained response occurs in only 30% to 40% of patients.[39,40] Although generally well-tolerated, side effects associated with cabergoline include nausea, orthostasis, headache, nasal congestion, constipation, nightmares, vivid dreams, and psychosis. The risk of cabergoline-associated cardiac valvulopathy (observed with higher doses used to treat Parkinson disease) has not been well-studied in lower doses typically used for the treatment of Cushing disease.[41]

The somatostatin analogs octreotide and lanreotide generally are ineffective in reducing ACTH secretion in Cushing disease. These two agents primarily target somatostatin receptor subtype 2 (sst_2), whereas pituitary adenomas predominantly express sst_5. Pasireotide, a somatostatin analog, exhibits a high affinity for sst_1, sst_2, sst_3, and, especially, sst_5 receptor subtypes. In a phase 3 study of 162 adults with Cushing disease and an elevated UFC, pasireotide administered at 600 or 900 μg injected subcutaneously twice daily reduced the median UFC by 50% by month 2; levels remained stable for the duration of the 12-month study.[42] Pasireotide is especially effective at normalizing UFC concentrations in patients whose baseline UFC is less than five times the upper limit of normal. Clinical signs and symptoms of Cushing disease are also improved as are blood pressure, weight, LDL cholesterol, and quality of life. Side effects are mostly GI in nature, although 50% to 70% of subjects experience an adverse event related to hyperglycemia; preexisting diabetes mellitus or impaired glucose tolerance increases the risk for these events. Notably, pasireotide increases glycated hemoglobin A1c by an average of 1.4% (0.014; 15 mmol/mol Hb) at 6 months and this effect may be sustained with long-term therapy,[43] likely due to impaired insulin secretion.[44]

Since coexpression of D_2 and sst_5 receptors is common in adrenocorticotropin-secreting adenomas, the combination of pasireotide and cabergoline may produce synergistic effects in reducing cortisol levels.[3] Limited data suggest that step-wise addition of cabergoline and ketoconazole in patients unresponsive to pasireotide may achieve normalization of UFC in the majority of patients; however, additional studies are needed to confirm the efficacy of this combination therapy. Potential drug-drug interactions exist with the combination of pasireotide and ketoconazole, and thus, the combination should be used with caution.[43,45,46]

Glucocorticoid-Receptor Blocking Agents

Mifepristone is a potent progesterone- and glucocorticoid-receptor antagonist that inhibits dexamethasone suppression and increases endogenous cortisol and ACTH levels in normal subjects.[26,30] Clinical experience and trial data in Cushing syndrome suggest that mifepristone is highly effective in reversing the manifestation of hypercortisolism, including hyperglycemia, hypertension, and weight gain.[47] Consequently, mifepristone has an FDA-approved indication for treatment of endogenous Cushing syndrome in patients who have type 2 diabetes or glucose intolerance, and who are not eligible for or have had poor response to surgery. However, because of its novel site of action, mifepristone induces a compensatory rise in ACTH and cortisol. Consequently, efficacy and toxicity monitoring must rely on clinical signs rather than laboratory assessments. Common adverse effects of mifepristone include fatigue, nausea, headache, arthralgia, peripheral edema, endometrial thickening (with or without vaginal bleeding), and significant reductions in serum potassium. Oral potassium supplementation or spironolactone can be effective in mitigating the latter adverse effect, although high doses may be required.[47]

Close monitoring of 24-hour UFC and serum cortisol is essential to detect treatment-induced adrenal insufficiency. Steroid secretion should be monitored with all of these drugs except mifepristone and steroid replacement given as needed. Whatever the choice, pharmacologic therapy in pituitary-dependent disease is mainly centered around patient stabilization prior to surgery or in patients waiting for potential response to other therapies.

Hyperaldosteronism

Excess aldosterone secretion, hyperaldoteronism, can be the result of either primary or secondary causes.[48–51] In primary hyperaldosteronism (PA), the stimulation for aldosterone secretion arises from within the adrenal gland. Conversely, extra-adrenal stimulation is classified as secondary aldosteronism.

Primary Aldosteronism

Etiology

The most common causes of PA include BAH (65%) and aldosterone-producing adenoma (APA; otherwise known as Conn syndrome) (30%). Rare causes include unilateral (primary) adrenal hyperplasia, adrenal cortex carcinoma, renin-responsive adrenocortical adenoma, and three forms of familial hyperaldosteronism (FH): FH type I, also known as glucocorticoid-remediable aldosteronism (GRA); FH type II, also known as familial occurrence of adenoma or hyperplasia type II; and FH type III.[48,50,51]

CLINICAL PRESENTATION

PA is present in approximately 10% of patients with hypertension and is a leading cause of secondary hypertension and treatment resistant hypertension. The disease is more common in women than in men, and diagnosis usually occurs between the third and sixth decades of life. Signs and symptoms can include arterial hypertension, which is often moderate to severe and resistant to pharmacologic intervention. Many patients also have hypokalemia (10%-40%), muscle weakness, fatigue, and headache. These features are nonspecific and many patients are asymptomatic. Historically, hypokalemia was considered a requisite feature for PA diagnosis; however, normokalemia exists frequently in patients and does not rule out PA. Unexplained new-onset of atrial fibrillation or other arrhythmias may also be indicative of PA.[52]

CLINICAL PRESENTATION: Primary Aldosteronism

Symptoms

- Patients may complain of muscle weakness, fatigue, paresthesias, and headache.

Signs

- Hypertension
- Tetany/paralysis
- Polydipsia/nocturnal polyuria

Laboratory Tests

- A plasma-aldosterone-concentration–to–plasma-renin-activity (PAC–to–PRA) ratio or aldosterone-to-renin ratio (ARR) greater than 30 ng/dL per ng/(mL·h) (830 pmol/L per mcg/(L·h) and a PAC greater than 15 ng/dL (420 pmol/L) is suggestive of PA.
- Common laboratory findings include suppressed PRA, elevated PAC, hypernatremia (>142 mEq/L [mmol/L]), hypokalemia, hypomagnesemia, elevated bicarbonate concentration (>31 mEq/L [mmol/L]), and glucose intolerance.

Confirmatory Tests

- Oral or IV saline loading, fludrocortisone suppression test (FST), and genetic testing

Diagnosis

Early diagnosis and treatment of PA are essential as patients with PA are at increased risk of adverse cardiovascular outcomes compared to patients with essential hypertension alone.[53] Diagnostic confirmation of PA is obtainable through screening, confirmatory tests, and subtype differentiation (Fig. 97-5). The discovery of the underlying etiology ensures proper treatment. Table 97-8 lists the various abnormalities that must be ruled out when hyperaldosteronism is suspected.

TABLE 97-8

Differential Diagnosis of Primary Aldosteronism

Disease	Plasma Renin Activity	Plasma Aldosterone Concentration	Blood Pressure
Primary aldosteronism	Low	High	High
Edematous disorders	High	High	Normal
Malignant hypertension	High	High	High
Congenital adrenal hyperplasia	Low	Low	High
Cushing syndrome	Low to normal	Low to normal	High
Liddle syndrome	Low	Low	High
Bartter syndrome	High	High	Low to normal
Licorice ingestion	Low	Low	High
Low-renin essential hypertension	Low	Low to normal	High

Initial diagnosis is made by screening patients with suspected PA. Any patient with a blood pressure greater than 150/100 mm Hg measured on three separate days and those meeting the criteria for treatment-resistant hypertension should be screened.[54] Additional patients at risk for PA include those with diuretic-induced hypokalemia, hypertension and adrenal incidentaloma, hypertension and sleep apnea, hypertension and a family history of early-onset hypertension or cerebrovascular accident at an age less than 40 years, and all patients with hypertension and a first-degree relative diagnosed with PA.

Screening for PA is most often done by using the PAC-to-PRA ratio, otherwise known as the ARR. An elevated ARR is highly suggestive of PA; however, an optimal cutoff ratio remains elusive because testing conditions (posture, time, current drug therapy, recent dietary salt intake), patient characteristics, and assay variability can significantly alter test results.[55] ARR cutoffs of 20 to 40 ng/dL per ng/(mL·h) (550 to 1100 pmol/L per (mcg/(L·h)) with an aldosterone concentration greater than 15 ng/dL (420 pmol/L) are used most often.[49,55–57]

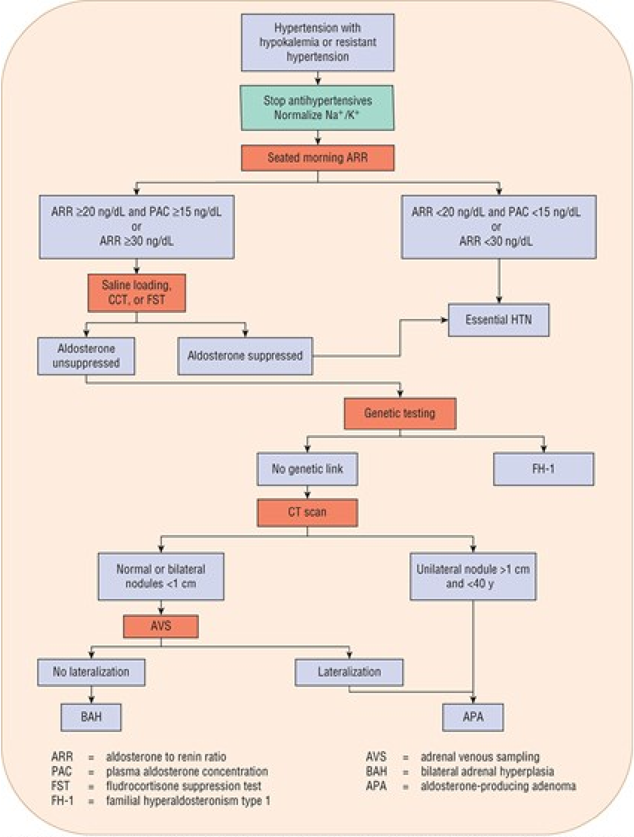
Following a positive ARR screening test, confirmatory testing must be performed to exclude false-positive cases. Confirmatory tests include the oral sodium loading test, saline infusion test (SIT), fludrocortisone suppression test (FST), and the captopril challenge test (CCT). Although individual tests can vary in sensitivity, specificity, and reliability, any test can be used depending on patient- and institution-specific considerations. FST generally is considered the most reliable but requires hospitalization. The SIT and CCT are both accurate alternatives to FST. However, a post-CCT evaluation of PAC is recommended to help interpret results of this confirmatory test.[58] Prior to performing these tests, potassium must be normalized and renin-angiotensin-aldosterone system (RAAS) inhibitors should be temporarily discontinued, if possible. Positive tests indicate autonomous aldosterone secretion under inhibitory pressures and are diagnostic for PA. After diagnosis, patients with confirmed PA before age 20 or with a family history of PA or strokes before age 40 should undergo genetic testing for GRA.[55]

Differentiating between an APA and BAH is imperative to formulate a proper treatment plan. Most adenomas are singular and small (<1 cm) and occur more often in the left adrenal gland than the right. Patients with APA generally have more severe hypertension, more profound hypokalemia, and higher plasma and urinary aldosterone concentrations compared with patients with BAH. Adrenal venous sampling (AVS) provides the most accurate means of differentiating unilateral from bilateral forms of PA. However, AVS is expensive, invasive, and often unavailable. CT scanning can detect most adenomas, although an incidentaloma can occasionally cause confusion. If CT scanning is inconclusive, AVS is performed to characterize lateralization.[49,59–61]

The underlying abnormality in BAH remains a mystery, but some investigators believe that a hormone factor stimulates the zona glomerulosa, resulting in increased sensitivity to angiotensin II. In contrast to those with an APA, patients with BAH are able to maintain control of the renin-angiotensin system, with little effect following doses of ACTH.

FIGURE 97-5

Algorithm for the diagnosis of primary aldosteronism. (ARR, aldosterone-to-renin ratio expressed in ng/dL per ng/(mL·h); HTN, hypertension; PAC, plasma aldosterone concentration [multiply values by 27.74 for units of pmol/L]).



Hypertension with hypokalemia or resistant hypertension
Stop antihypertensives Normalize Na⁺/K⁺
Seated morning ARR
ARR ≥20 ng/dL and PAC ≥15 ng/dL or ARR ≥30 ng/dL
ARR <20 ng/dL and PAC <15 ng/dL or ARR <30 ng/dL
Saline loading, CCT, or FST

TREATMENT

BAH-Dependent Aldosteronism

Aldosterone-receptor antagonists are the treatment of choice in BAH. Drug dosing and monitoring parameters can be found in Tables 93-9 and 93-10. Spironolactone, a nonselective aldosterone-receptor antagonist, competes with aldosterone for binding at the aldosterone receptor, thus preventing the negative downstream effects of aldosterone-receptor activation. Additionally, spironolactone is capable of inhibiting aldosterone synthesis within the adrenal gland; however, the magnitude of inhibition is relatively small and the effect only occurs above recommended doses.[62] Spironolactone is available in oral form, with most patients responding to doses between 25 and 400 mg/day. The clinician should wait 4 to 8 weeks before reassessing the patient for urinary electrolytes and blood pressure control. Adverse effects of spironolactone are dose-dependent and include GI discomfort, impotence, gynecomastia, menstrual irregularities, and hyperkalemia. Gynecomastia and menstrual irregularities observed with spironolactone therapy arise from activity at androgen and progesterone receptors and inhibition of testosterone biosynthesis. Additionally, because salicylates increase the renal secretion of canrenone, the active metabolite of spironolactone, patients should be advised to avoid concomitant therapy with salicylates. In patients intolerant of spironolactone, alternative options include eplerenone and amiloride.[50,51,63–65]

TABLE 97-9

Drug Dosing in the Treatment of Hyperaldosteronism

Drug	Initial Dose	Usual Range	Special Populations	Comments
Amiloride	5 mg twice daily	20 mg/day in two divided doses	CrCl 10-50 mL/min (0.17-0.84 mL/s): reduce dose by 50%; CrCl <10 mL/min (0.17 mL/s): CI	Maximum: 30 mg/day
Eplerenone>	50 mg once daily>	100-300 mg/day in single or divided doses; titrate at 4- to 8-week intervals	CrCl <30 mL/min (0.5 mL/s): CI	Maximum: 300 mg/day
Spironolactone	25 mg once daily	100-400 mg/day in single or divided doses; titrate at 4- to 8-week intervals	CrCl 10-50 mL/min (0.17-0.84 mL/s): extend dosing interval to once daily; CrCl <10 mL/min (0.17 mL/s): CI	Maximum: 400 mg/day

CI, contraindicated; CrCl, creatinine clearance.

TABLE 97-10

Drug Monitoring in the Treatment of Hyperaldosteronism

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Amiloride	Electrolyte abnormalities (hyperkalemia), hypotension, nausea, vomiting, diarrhea, headache	Serum creatinine, serum potassium, blood pressure	Electrolyte abnormalities (hyperkalemia) more pronounced with reduced renal function
Eplerenone	Electrolyte abnormalities (hyperkalemia), hypotension, dizziness, headache; gynecomastia and menstrual irregularities are uncommon	Serum creatinine, serum potassium, blood pressure	Electrolyte abnormalities (hyperkalemia) more pronounced with reduced renal function. CYP3A4 substrate; avoid use with potent CYP3A4 inhibitors
Spironolactone	GI discomfort, impotence, gynecomastia, menstrual irregularities, electrolyte abnormalities (hyperkalemia), hypotension	Serum creatinine, serum potassium, blood pressure	Electrolyte abnormalities (hyperkalemia) more pronounced with reduced renal function

Eplerenone is a selective aldosterone-receptor antagonist with high affinity for the aldosterone receptor and low affinity for androgen and progesterone receptors. Consequently, eplerenone elicits fewer sex steroid–dependent effects than spironolactone. Randomized controlled trial data have been inconclusive with regard to whether eplerenone achieves similar blood pressure reductions to spironolactone and there are limited long-term data comparing these agents.[66,67] Eplerenone dosing starts at 50 mg daily, with titration to 50 mg twice a day; some patients may require total daily doses as high as 200 to 300 mg.[63] Titration should occur at 4- to 8-week intervals. In addition, eplerenone is a substrate of CYP3A4 and should not be taken with potent CYP3A4 inhibitors. Eplerenone is the preferred aldosterone antagonist during pregnancy since spironolactone can cause ambiguous genitalia in a male fetus.[68]

Amiloride, a potassium-sparing diuretic, is dosed at 5 mg twice a day up to 30 mg/day if necessary. Amiloride is less effective than spironolactone and patients often require additional therapy to adequately control blood pressure. Additional second-line options include calcium channel blockers, ACE inhibitors, and diuretics such as chlorthalidone, although all lack outcome data in PA.[61,64] However, some agents (eg, diuretics, calcium channel blockers) can promote a reactive rise in PRA, ultimately leading to increased aldosterone levels and potentially worsening PA. A prudent strategy would be to use these agents only in combination with RAAS inhibitors to mitigate the downstream aldosterone effects of any increase in PRA.

Initiation of these drugs, particularly spironolactone and eplerenone, should be accompanied by close monitoring of blood pressure. Both agents can cause significant reductions in blood pressure and patients may need to reduce the dose or discontinue other antihypertensive drugs in their regimens.

APA-Dependent Aldosteronism

The treatment of choice for APA-dependent aldosteronism remains laparoscopic resection of the adenoma.[69] Nearly 100% of patients show blood pressure improvement and up to 72% are permanently cured.[65,70] Because APAs are small and often occur in multiples, resection should target the entire adrenal gland. In successful cases, blood pressure control is achieved in 1 to 3 months. Medical management with an aldosterone receptor antagonist is often effective in this population if surgery is contraindicated. However, medical management may be significantly more expensive than unilateral resection.

Glucocorticoid-Remediable Aldosteronism

Glucocorticoids are very effective in treating GRA.[32] Low doses of long-acting glucocorticoids are used (0.125-0.5 mg/day of dexamethasone or 2.5-5 mg/day of prednisone) because complete suppression of ACTH-stimulated aldosterone release is unnecessary. If blood pressure fails to normalize with glucocorticoid therapy alone, the addition of spironolactone, eplerenone, or amiloride may help control symptoms.[49]

Secondary Aldosteronism

Secondary aldosteronism results from an appropriate response to excessive stimulation of the zona glomerulosa by an extra-adrenal factor, usually the renin-angiotensin system. Excessive potassium intake can promote aldosterone secretion as well as oral contraceptive use, pregnancy (aldosterone secretion 10 times normal by the third trimester), and menses. Congestive heart failure, cirrhosis, renal artery stenosis, and Bartter syndrome also can lead to elevated aldosterone concentrations.

Treatment of secondary aldosteronism is dictated by the etiology. Control or correction of the extra-adrenal stimulation of aldosterone secretion should resolve the disorder. Medical therapy with spironolactone is the mainstay of treatment until an exact etiology can be identified.

HYPOFUNCTION OF THE ADRENAL GLAND

Hypofunction of the adrenal gland can affect any or all adrenal hormones, depending on the etiology of the disorder. However, hypofunction does not always lead to insufficient production of adrenal hormones. Some types of adrenal hypofunction can lead to excess production of certain hormones.

Addison Disease

⑦ Primary adrenal insufficiency, or Addison disease, most often involves the destruction of all regions of the adrenal cortex. Deficiencies arise in cortisol, aldosterone, and the various androgens, and levels of CRH and ACTH increase in a compensatory manner. In developed countries, autoimmune dysfunction is responsible for most cases (80%-90%), whereas tuberculosis predominates as the cause in developing countries. Approximately 50% of patients with autoimmune etiologies present with one or more concomitant autoimmune disorders, usually involving other endocrine organs. Autoimmune thyroid disorders (eg, Hashimoto thyroiditis or Graves' disease) are the most common, but the ovaries, pancreas, parathyroid gland, and organs of the GI system can also be affected. This polyglandular failure syndrome, termed autoimmune polyendocrine syndrome (APS), is associated with the idiopathic etiology only and has not been seen with adrenal insufficiency associated with tuberculosis or other invasive diseases. Medications that inhibit cortisol synthesis (ketoconazole) or accelerate cortisol metabolism (phenytoin, rifampin, phenobarbital) can also cause primary adrenal insufficiency.[71]

⑧ Secondary insufficiency is characterized by reduced glucocorticoid production secondary to decreased ACTH levels. Low levels of ACTH most commonly result from exogenous steroid use, leading to suppression of the HPA axis and decreased release of ACTH, as well as impaired androgen and cortisol production. These effects occur with oral, inhaled, intranasal, and topical glucocorticoid administration.[72–74] Moreover, mirtazapine and progestins, such as medroxyprogesterone acetate and megestrol acetate, have been reported to induce secondary adrenal insufficiency.[75,76] Chronic suppression also can result in atrophy of the anterior pituitary and hypothalamus, impairing recovery of function if the exogenous steroid is reduced. Endogenous secondary insufficiency can occur with tumor development in the hypothalamic-pituitary region. Secondary disease classically presents with normal concentrations of mineralocorticoids since the zona glomerulosa is controlled by the renin-angiotensin system rather than ACTH levels.

Approximately 90% of the adrenal cortex must be destroyed before the symptoms of adrenal insufficiency become clinically manifest.[77] Etiologies for both primary and secondary insufficiency are listed in Table 97-11. Adrenal hemorrhage can result from multiple etiologies including traumatic shock, coagulopathies, ischemic disorders, and other situations of severe stress, but septicemia is the most common. Symptoms include truncal pain, fever, shaking, chills, hypotension preceding shock, anorexia, headache, vertigo, vomiting, rash, psychiatric symptoms, abdominal rigidity or rebound, and death in 6 to 48 hours if not treated. The most common organisms found on autopsy are *Neisseria meningitidis*, *Pseudomonas aeruginosa*, *Streptococcus pneumoniae*, Group A *Streptococcus*, and *Haemophilus influenzae*.[77,78]

TABLE 97-11

Etiologies of Primary and Secondary Adrenal Insufficiency

Primary Insufficiency	Secondary Insufficiency
Slow onset	Craniopharyngioma
Acquired immunodeficiency syndrome	Cure of Cushing syndrome
Adrenomyeloneuropathy	Empty sella syndrome
Adrenoleukodystrophy	Tumors of the third ventricle
Amyloidosis	Histiocytosis
Autoimmune adrenalitis[a]	Hypothalamic tumors
Bilateral adrenalectomy	Hypopituitarism
Congenital adrenal hypoplasia	Long-term corticosteroid administration
Hemochromatosis	Lymphocytic hypophysitis
Isolated glucocorticoid deficiency	Pituitary surgery, radiation, or tumor
Metastatic neoplasia	Sarcoidosis
Systemic fungal, bacterial, or viral infections, tuberculosis[b]	Medications—progestins and glucocorticoid discontinuation
Medications—ketoconazole, etomidate, rifampin, phenytoin, phenobarbital	Postpartum pituitary necrosis Necrotic or bleeding pituitary macroadenoma
Fast onset	
Adrenal thrombosis, hemorrhage, sepsis, trauma, or necrosis	Head trauma, lesions of the pituitary stalk, pituitary or adrenal surgery for Cushing syndrome

[a] Approximately 70% of cases.

[b] Approximately 20% of cases.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Adrenal Insufficiency

Symptoms

- Patients commonly complain of weakness, weight loss, GI symptoms, craving for salt, headaches, memory impairment, depression, and postural dizziness.
- Early symptoms of acute adrenal insufficiency also include myalgias, malaise, and anorexia. As the situation progresses, vomiting, fever, hypotension, and shock will develop.

Signs

- Increased pigmentation
- Hypotension (postural)
- Fever
- Decreased body hair
- Vitiligo
- Features of hypopituitarism (amenorrhea and cold intolerance)

Laboratory Tests

- The short cosyntropin stimulation test can be used to assess patients suspected of hypercortisolism.

Other Diagnostic Tests

- Other tests include the insulin hypoglycemia test, the metyrapone test, and the CRH stimulation test.

Diagnosis

Distinguishing Addison disease from secondary insufficiency is difficult; however, the following guidelines may be helpful:

1. Hyperpigmentation, commonly found in areas of skin exposed to increased friction, is seen only in Addison disease because of excess secretion of ACTH and other proopiomelanocortin (POMC) peptides that induce melanocyte-stimulating hormone production. Secondary adrenal insufficiency is fundamentally characterized by deficient ACTH and POMC peptide secretion and a correspondingly low level of melanocyte-stimulating hormone production. In fact, some patients with secondary insufficiency may exhibit pale-colored skin secondary to hypopigmentation.
2. Aldosterone secretion usually is preserved in secondary insufficiency.
3. Weight loss, dehydration, hyponatremia, hyperkalemia, and elevated blood urea nitrogen are common in Addison disease.
4. Addison disease will have an abnormal response to the short corticotropin stimulation test. Plasma ACTH levels are usually elevated (400-2,000 pg/mL [88-440 pmol/L]) in primary insufficiency, versus low to normal (5-50 pg/mL [1.1-11 pmol/L]; see Table 97-3) in secondary insufficiency. A normal corticotropin stimulation test does not rule out secondary adrenal insufficiency, particularly in mild cases.

The short corticotropin stimulation test, also known as the cosyntropin stimulation test, can be used to assess patients suspected of hypocortisolism. A 250 μg dose of synthetic ACTH intravenously or intramuscularly to the patient and the serum cortisol is measured at immediately prior to and 30 to 60 minutes after the injection. A resulting cortisol concentration ≥18 μg/dL (500 nmol/L) rules out adrenal insufficiency.[79] Because 250 μg represents a massive supraphysiologic dose, this test can elicit normal, elevated cortisol responses in some cases of mild secondary insufficiency. Thus, some suggest that higher cutoff values (≥22 μg/dL [610 nmol/L]) should be used to prevent false-negative test results.[80] Alternatively, a low-dose corticotropin stimulation test, using 1 µg of synthetic ACTH, can achieve similar results to the standard dose test. Neither test is very effective in ruling out secondary insufficiency.[81] Other tests include the insulin hypoglycemia test, the metyrapone test, and the CRH stimulation test.[71]

The standard cutoffs described above are of limited use in acutely ill patients.[71] Severe infection, trauma, burns, illnesses, or surgery can increase cortisol production by as much as a factor of 6, making the recognition of adrenal insufficiency in this population extremely difficult. In the critically ill, a random cortisol concentration below 15 µg/dL (415 nmol/L) is suggestive of adrenal insufficiency, whereas a concentration greater than 34 µg/dL (940 nmol/L) suggests that adrenal insufficiency is unlikely.[71] For patients who fall between these two values, a poor response to corticotropin (<9 µg/dL [250 nmol/L] increase in plasma cortisol from baseline at 30 or 60 minutes) indicates the possibility of adrenal insufficiency and a need for corticosteroid supplementation.[71] A hypoproteinemic patient (albumin <2.5 g/dL [25 g/L]) will have markedly lower CBG, which can underestimate the actual free fraction of cortisol. These patients may benefit from measurement of free cortisol, although the assay may not be routinely available.[71]

TREATMENT

Treatment of Addison disease must include adequate patient education, so that the patient is aware of treatment complications, the expected outcome, consequences of missed doses, and drug side effects. The agents of choice are hydrocortisone and cortisone acetate administered two or three times daily. The treatment goal is to establish the lowest effective dose mimicking the normal diurnal adrenal rhythm.[79] Twice-daily dosing is usually adequate depending on the agent used. Once-daily prednisolone is an alternative when adherence to a multi-dose regimen is a concern.

Endogenous cortisol production varies between 5 and 10 $mg/m^2/day$.[82] Hence, the classically recommended 12 to 15 $mg/m^2/day$ dose for cortisol supplementation will be excessive in most patients. Starting doses to properly mimic endogenous cortisol production are 15 to 25 mg of hydrocortisone daily, which is roughly equal to 20 to 35 mg of cortisone acetate daily, or 3 to 5 mg of prednisolone daily.[71,82] For hydrocortisone or cortisone, the majority of the dose (67%) is given in the morning and the remainder (33%) is given 6 to 8 hours later to duplicate the normal circadian rhythm of cortisol production. Continuous infusion of glucocorticoids delivered via infusion pump may provide a more physiological circadian maintenance of ACTH and cortisol concentration when compared to conventional oral replacement.[83] Since no laboratory test adequately determines the appropriateness of dosing, the patient's symptoms should be monitored every 6 to 8 weeks to assess proper glucocorticoid replacement. Monitoring parameters should include body weight, postural blood pressures, subjective energy levels, and signs of frank glucocorticoid excess.

In primary insufficiency, fludrocortisone acetate can be used to supplement mineralocorticoid loss. For most patients, a dose of 0.05 to 0.2 mg by mouth once a day is adequate to maintain volume status. If parenteral therapy is needed, 2 to 5 mg of deoxycorticosterone trimethylacetate in oil intramuscularly every 3 to 4 weeks can be substituted. Mineralocorticoid replacement attenuates the development of hyperkalemia, and patients on fludrocortisone therapy do not need to restrict salt intake. However, mineralocorticoid replacement may be unnecessary in some primary cases because glucocorticoids, particularly at large doses, also bind to mineralocorticoid receptors. For example, a daily dose of hydrocortisone 40 to 50 mg has similar mineralocorticoid effects to 0.1 mg of fludrocortisone. Adverse effects must be monitored closely and include gastric upset, edema, hypertension, hypokalemia, insomnia, excitability, and diabetes mellitus. In addition, patient weight, blood pressure, and ECG should be monitored regularly.[71]

Most adrenal crises occur secondary to glucocorticoid dose reduction or lack of stress-related dose adjustments. Patients receiving corticosteroid replacement therapy should receive an additional 5 to 10 mg of hydrocortisone shortly before strenuous activities such as exercise.[71] Likewise, during times of severe physical stress such as febrile illnesses or injury, patients should be instructed to double their daily dose until recovery.[71,84] For major trauma, surgery, or in critically ill patients, larger doses—up to 10 times the usual daily dose—may be required.[71] Parenteral therapy should be used for patients experiencing diarrhea or vomiting. In patients with concomitant, newly diagnosed, or uncontrolled hypothyroidism, thyroid replacement should take place only after adequate glucocorticoid replacement as euthyroidism can trigger an adrenal crisis by accelerating cortisol metabolism.[79]

The endpoint of therapy is difficult to assess in most patients, but a reduction in excess pigmentation is a good clinical marker. The development of features of Cushing syndrome indicates excessive replacement. Treatment of secondary adrenal insufficiency is similar to primary disease treatment, except that mineralocorticoid replacement usually is unnecessary. Patient education is paramount with emphasis placed on the medication regimen and adrenal crisis prevention.

Acute Adrenal Insufficiency

Adrenal crisis, or Addisonian crisis, is characterized by an acute adrenocortical insufficiency and represents a true endocrine emergency. Although no universally accepted definition for adrenal crisis exists, major clinical features include volume depletion and hypotension that resolves within one to two hours after parenteral glucocorticoid administration.[85] Anything that increases adrenal requirements dramatically can precipitate an adrenal crisis. Stressful situations, surgery, infection, and trauma all are potential triggering events, especially in the patient with some underlying adrenal or pituitary insufficiency. The most common cause of an adrenal crisis is HPA-axis suppression brought on by abrupt withdrawal of chronic glucocorticoid use.

Treatment of adrenal crisis involves the administration of parenteral glucocorticoids. Hydrocortisone is the agent of choice owing to its combined glucocorticoid and mineralocorticoid activity. Hydrocortisone is initially administered at a dose of 100 mg IV through rapid infusion, followed by 200 mg of hydrocortisone over 24 hours via a continuous infusion or a 50mg intermittent bolus every 6 hours.[71] Intravenous administration is continued for an additional day at a reduced dose of 100 mg over 24 hours, at which time if the patient is stable, oral hydrocortisone can be administered at a dose of 50 mg every 6 to 8 hours, followed by tapering to the individual's chronic replacement needs. Fluid replacement often is required and can be accomplished with dextrose 5% in normal saline solution (D_5NS) at a rate to support blood pressure. If therapy is needed for hypoglycemia, dextrose 25% in water ($D_{25}W$) can be infused at a dose of 2 to 4 mL/kg (maximum single dose of 25 g dextrose). During initial treatment for adrenal crisis, mineralocorticoid replacement generally is unnecessary because of hydrocortisone's mineralocorticoid activity. If hyperkalemia is present after the hydrocortisone maintenance phase, additional mineralocorticoid supplementation can be achieved with 0.1 mg of fludrocortisone acetate daily.

Patients with adrenal insufficiency should be instructed to carry a card or wear a bracelet or necklace, such as MedicAlert, that contains information about their condition. Additionally, patients should have easy access to injectable hydrocortisone or glucocorticoid suppositories in case of an emergency or during times of physical stress, such as febrile illness or injury.[71]

Hypoaldosteronism

Hypoaldosteronism is rare and usually associated with low-renin status (hyporeninemic hypoaldosteronism), diabetes, complete heart block, or severe postural hypotension, or it can occur postoperatively following tumor removal. Hypoaldosteronism can be part of a multi-hormonal insufficiency or a stand-alone defect. In nonselective hypoaldosteronism, generalized adrenocortical insufficiency is the most likely etiology (see Addison Disease). In selective hypoaldosteronism, insufficient aldosterone levels are precipitated by a specific defect in the stimulation of adrenal aldosterone secretion, with 21-hydroxylase deficiency being the most common. Pseudohypoaldosteronism results from a defect in peripheral aldosterone action, whether from peripheral resistance or a reduced number of functional aldosterone receptors.

Laboratory analysis reveals hyponatremia, hyperkalemia, or both. Patients often will present with hyperchloremic metabolic acidosis. In most cases, the deficiency is in mineralocorticoid production and fludrocortisone given 0.05 to 0.2 mg daily is usually effective. Patients should be monitored for blood pressure response as well as electrolyte status.

Congenital Adrenal Hyperplasia

Because many enzyme systems are needed to complete the complex cholesterol-to-cortisol pathway, enzyme deficiencies can lead to disruptions of the normal cascade of events (see Fig. 97-2). This group of enzyme disorders is collectively referred to as congenital adrenal hyperplasia (CAH) because of the resultant chronic adrenal gland stimulation that occurs following enzyme deficiency.[71,86,87] The most frequent cause of CAH is steroid 21-hydroxylase deficiency, accounting for more than 90% of cases. Any enzyme deficiency is capable of affecting any one or all three of the steroid pathways. Therefore, treatment focuses on the replacement of the deficient hormone, psychological support, and surgical repair of the external genitalia in female patients.[88] Pediatric patients receiving glucocorticoid replacement (eg, with hydrocortisone and fludrocortisone) should be monitored for adverse outcomes, especially incident hypertension and decreased bone mineral density.[89,90] Six of the most common enzyme deficiencies are outlined briefly in Table 97-12.

TABLE 97-12

Congenital Adrenal Hyperplasia

Enzyme Deficiency (Disorder)	Symptoms	Laboratory Tests	Comments
21-Hydroxylase (nonvirilizing CAH)	Enlarged female genitalia and adrenal gland (caused by cholesterol)	All steroids are low in blood and urine	Poor prognosis for infants
17-Hydroxylase (nonvirilizing CAH)	Hypertension usually present	Low concentrations of cortisol and estrogens	Mineralocorticoid replacement is not necessary
21-Hydroxylase (virilizing CAH)	Pubertal irregularities (acne, early pubic hair, voice lowering, and increased muscularity); mature normally with replacement	High progesterone, renin, 17-hydroxyprogesterone, and ACTH; low cortisol, sodium, and aldosterone	Most common form of CAH (90% of total), incidence of 1:10,000; monitor growth velocity, bone age, renin, and 17-hydroxyprogesterone
11-Hydroxylase (virilizing CAH)	Hypertension secondary to high deoxycortisol and virilism from androgen excess; mistaken for Cushing, but no glucose intolerance	Low plasma cortisone and aldosterone; high ACTH and MSH concentrations	Second most common form of CAH (9% of total), the incidence of 1:100,000; the final step in the biosynthesis of corticosterone and cortisol; found only in the adrenal cortex
3-Hydroxysteroid dehydrogenase (mixed CAH)	Both cortisol and aldosterone deficiencies	Decreased aldosterone, cortisol, estrogens, and androgens; increased pregnenolone and cholesterol	The defect affects both adrenals and gonads
18-Hydroxysteroid dehydrogenase (corticosterone methyloxidase deficiency)	Hypotension	Restricted to zona glomerulosa; sole aldosterone defect; hyponatremia, hyperkalemia, increased renin	Mineralocorticoid replacement without glucocorticoid replacement

MSH, melanocyte-stimulating hormone.

Adrenal Virilism

9 Virilism, excessive secretion of androgens from the adrenal gland, commonly occurs as a result of congenital enzyme defects. Depending on the enzyme deficiency, patients accumulate excess levels of a variety of androgens, most notably testosterone. The condition affects women more often than men, with hirsutism being the dominant feature. Additional coexisting features can include voice deepening, acne, increased muscle mass, menstrual abnormalities, clitoral enlargement, redistribution of body fat and loss of female body contour, breast atrophy, and hair recession and crown balding.[91]

Treatment of virilism centers on the suppression of the pituitary-adrenal axis with exogenous glucocorticoids. In adults, the usual steroids used are dexamethasone (0.25-0.5 mg), prednisone (2.5-5 mg), or hydrocortisone (10-20 mg).[92]

Hirsutism

Women presenting with hirsutism exhibit excess terminal hair growth in an androgen-dependent distribution. Such growth has obvious cosmetic consequences, but also can adversely affect quality of life and psychological well-being.[93] Most cases of hirsutism occur in women with some degree of excess androgen production. Androgen excess can be derived from either the ovaries or the adrenal glands, or rarely from pituitary disorders. Polycystic ovarian syndrome (PCOS) is responsible for most cases of ovarian excess and is the most common cause of hirsutism.[94] CAH accounts for 5% of cases while adrenal and ovarian tumors cause hyperandrogenemia in 0.2% of women.

Cosmetic approaches generally are tried first, with repeated photoepilation offering the greatest long-term success.[95] If these approaches are unsuccessful, subsequent treatment should include pharmacologic intervention. Oral contraceptives are the treatment of choice in most hirsute women, particularly in those requiring concurrent contraception. If oral contraceptives are used, a progestin with low androgen activity (norethindrone, ethynodiol diacetate) or antiandrogenic activity (drospirenone) should be chosen. Other antiandrogens, including spironolactone and finasteride, can supplement or replace oral contraceptive therapy in women who cannot or choose not to conceive. Antiandrogens can take 6 to 12 months to alleviate hirsutism and treatment should be continued for 2 years, followed by a slow dose reduction.[96] Dexamethasone (and other glucocorticoids) can be modestly effective if the androgen source is adrenal, but can induce cushingoid symptoms even at doses of 0.5 mg/day.

Gonadotropin-releasing hormone can be an effective adjunct or alternative to oral contraceptives if the source of androgen is ovarian. However, these products generally are not recommended due to excessive costs, injectable-only routes of administration, and adverse effects resulting from estrogen deficiency. Additionally, insulin sensitizers, such as metformin or thiazolidinediones, can show modest metabolic and glycemic improvement in women with PCOS, but their routine use is not recommended due to their limited impact on hirsutism, acne, and infertility.[94]

Eflornithine hydrochloride, an irreversible ornithine decarboxylase inhibitor, moderately reduces the rate of hair growth but does not remove hair already present. The drug is available as a topical cream applied as a thin layer to the affected area twice daily, at least 8 hours apart. Reduction in unwanted hair can be noted within 6 to 8 weeks with a maximal effect at 8 to 24 weeks; therapy must be continued indefinitely to prevent hair regrowth.[92,96] Skin irritation can occur that resolves on discontinuation.

PRINCIPLES OF GLUCOCORTICOID ADMINISTRATION

The term *glucocorticoid* was initially given to these agents to describe their glucose-regulating properties. However, carbohydrate metabolism is only one of the myriad effects exhibited by steroids. The activity produced by these drugs is a function of the receptor activated (glucocorticoid vs mineralocorticoid), the location of the receptor, as well as the agent and dose prescribed.

The mechanism of action of glucocorticoids is complex and not fully known. The glucocorticoid enters the cell through passive diffusion and binds to its specific receptor. Between 5,000 and 100,000 receptors exist in each cell. Steroids exhibit various binding affinities to the vast number of receptors in almost every tissue and therefore elicit a wide variety of biologic effects.

Following receptor binding, a structural change occurs in the receptor, known as *activation*. After activation, the receptor–steroid complex binds to deoxyribonucleic acid sites in the cell called *glucocorticoid response elements* (GREs). This binding alters nearby gene expression and stimulates or, in some cases, inhibits transcription of specific mRNAs. Consequently, the resulting protein, which produces the stimulatory or inhibitory glucocorticoid action, varies according to the tissue and cell type in which the glucocorticoid receptor exists.

Pharmacokinetic properties of the glucocorticoids vary by agent and route of administration. In general, most orally administered steroids are well absorbed. Water-soluble agents are more rapidly absorbed following intramuscular injection than are lipid-soluble agents. Intravenous administration is recommended when a quick onset of action is needed. A summary of these agents is provided in Table 97-13.

TABLE 97-13

Relative Potencies of Glucocorticoids

Glucocorticoid	Anti-inflammatory Potency	Equivalent Potency (mg)	Approximate Half-Life (min)	Sodium-Retaining Potency
Cortisone	0.8	25	30	2
Hydrocortisone	1	20	90	2
Prednisone	3.5	5	60	1
Prednisolone	4	5	200	1
Triamcinolone	5	4	300	0
Methylprednisolone	5	4	180	0
Betamethasone	25	0.6	100-300	0
Dexamethasone	30	0.75	100-300	0

In addition to causing iatrogenic Cushing syndrome, systemic steroids can lead to increased susceptibility to infection, osteoporosis, sodium retention with resultant edema, hypokalemia, hypomagnesemia, cataracts, peptic ulcer disease, seizures, and generalized suppression of the HPA axis. Long-term complications tend to be insidious and less likely to respond to steroid withdrawal.

Suppression of the HPA axis is a major concern whenever systemic steroids are tapered or withdrawn. Single doses of glucocorticoids can prevent the axis from responding to major stressors for several hours. In general, steroid administration at a high dose for long periods of time causes suppression of the axis. However, the possibility of suppression occurs any time the patient is exposed to supraphysiologic steroid doses.[11,97] Symptoms of steroid withdrawal resemble those seen in a patient with adrenocortical deficiency.

A variety of recommendations for steroid tapering are available.[11,98–100] In general, patients who have been on long-term steroid therapy will need to be gradually withdrawn toward physiologic doses over months. On average, the normal adult produces approximately 10 to 30 mg of cortisol per day with the peak concentration occurring around 8:00 am. As the steroid or steroid-equivalent dose approaches the 20- to 30-mg level, the taper should be slowed and the patient checked for axis function. The primary modes to test HPA integrity are the ACTH test, either high or low dose, or a morning (8:00 am) serum cortisol. A normal morning serum cortisol (>20 μg/dL [550 nmol/L]) or a normal ACTH test indicates that daily steroid maintenance therapy may be discontinued. If morning serum cortisol is between 3 and 20 μg/dL (85 and 550 nmol/L), the ACTH or CRH stimulation test can be useful in the assessment of pituitary-adrenal function.[11] A morning cortisol less than 3 μg/dL (85 nmol/L) indicates axis suppression and the need for continued replacement therapy. Suppression can persist for up to a year in some patients. Caution should be used to prevent disease exacerbation during the steroid taper and to avoid the need for another course of high-dose steroids.

Alternate-day therapy (ADT) regimens have been promoted as a means to lessen the impact of prolonged steroid administration.[11,100] ADT theoretically minimizes the hypothalamic-pituitary suppression as well as some of the adverse effects seen with once-daily therapy. This hypothetical advantage may be especially pertinent in treating children and young adults, in whom growth suppression is a major concern. ADT is not recommended for initial management, but rather in the management of the stabilized patient who needs long-term therapy. The patient is exposed to "on" and "off" days, with the "on" day dose gradually increased corresponding with a dose reduction in the "off" day dose over a period of 14 days. After 2 weeks, no medication is taken on "off" days. Not all patients will have equivalent disease control on ADT, and it should be avoided in certain indications.[11,100]

EVALUATION OF THERAPEUTIC OUTCOMES

Successful glucocorticoid therapy involves counseling and monitoring the patient, as well as recognizing complications of therapy (Table 97-14). The risk-to-benefit ratio of glucocorticoid administration should always be considered, especially with concurrent disease states such as hypertension, diabetes mellitus, peptic ulcer disease, and uncontrolled systemic infections.

TABLE 97-14

Appropriate Use of Glucocorticoid Therapy

Monitoring	Glucose concentrations (serum and urine) Electrolytes (serum and urine) Ophthalmologic examinations Stool tests for occult blood loss Growth and development (children and adolescents)
Patient Education	Take with food to minimize GI discomfort Never discontinue medication on your own; check with your physician; gradual dose reduction is usually necessary Carry or wear medical identification indicating that you are on long-term glucocorticoid therapy Dosage increases can be necessary at times of increased stress (surgery or emergency treatments) Be aware of potential side effects (ie, visual disturbances, bruising, and delayed wound healing) What to do if you miss a dose: If your dosing schedule is: *Every other day*: Take as soon as possible if remembered that morning. If not remembered until later, skip that day. Take the next morning, and then skip the following day *Every day*: Take as soon as possible, but skip if almost time for the next dose. Never double doses
Recognizing complications	Early in therapy and essentially unavoidable: insomnia, enhanced appetite, weight gain Common in patients with underlying risk factors: hypertension, diabetes mellitus, peptic ulcer disease Long-term intense treatment: cushingoid habitus, hypothalamic pituitary-adrenal suppression, impaired wound healing Delayed and insidious: cataracts, atherosclerosis Rare and unpredictable: psychosis, glaucoma, pancreatitis

ABBREVIATIONS

ACTH	adrenocorticotropic hormone
ADT	alternate-day therapy
ALP	alkaline phosphatase
ALT	alanine aminotransferase
APA	aldosterone-producing adenoma
APS	autoimmune polyendocrine syndrome
ARR	aldosterone-to-renin ratio

AST	aspartate aminotransferase
AVS	adrenal venous sampling
BAH	bilateral adrenal hyperplasia
CAH	congenital adrenal hyperplasia
CBG	corticosteroid-binding globulin
CCT	captopril challenge test
CHD	coronary heart disease
CNS	central nervous system
CrCl	creatinine clearance
CRH	corticotropin-releasing hormone
CT	computed tomography
CYP	cytochrome P450
D_5NS	dextrose 5% in normal saline solution
$D_{25}W$	dextrose 25% in water
DDT	dichlorodiphenyltrichloroethane
DST	dexamethasone suppression test
ECG	electrocardiogram
FDA	Food and Drug Administration
FH	familial hyperaldosteronism
FST	fludrocortisone suppression test
GABA	γ-aminobutyric acid
GI	gastrointestinal
GRA	glucocorticoid-remediable aldosteronism
GRE	glucocorticoid response element
HPA	hypothalamic–pituitary–adrenal
INR	international normalized ratio

IPSS	inferior petrosal sinus sampling
IRMA	immunoradiometric assay
JVS	jugular venous sampling
LDL	low-density lipoprotein
MRI	magnetic resonance imaging
PA	primary aldosteronism
PAC	plasma aldosterone concentration
PAC-to-PRA	plasma-aldosterone-concentration–to–plasma-renin-activity
PCOS	polycystic ovarian syndrome
POMC	proopiomelanocortin
PRA	plasma renin activity
RAAS	renin-angiotensinaldosterone system
RIA	radioimmunoassay
SIT	saline infusion test
sst	somatostatin receptor subtype
UFC	urinary free cortisolx

SELF-ASSESSMENT QUESTIONS

1. Aldosterone is synthesized in the:

A. Zona glomerulosa.

B. Zona fasciculata.

C. Zona reticularis.

D. Medulla.

2. Glucocorticoids regulate their own secretion by inhibiting the pituitary secretion of:

A. Corticotropin-releasing hormone.

B. Adrenocorticotropic hormone.

C. Melanocyte-stimulating hormone.

D. Renin.

3. The majority of cases of ACTH-dependent Cushing syndrome are caused by

A. Adrenal carcinoma.

B. Primary pigmented nodular adrenal disease.

C. Adrenal adenoma.

D. Pituitary adenoma.

4. In a 52-year-old male patient with cushingoid habitus, elevated serum and urinary cortisol, very high serum ACTH, no suppression of cortisol in response to low-dose DST, normal pituitary MRI, and no gradient on inferior petrosal sinus sampling (IPSS), the most likely diagnosis would be Cushing syndrome secondary to:

A. Adrenal carcinoma.

B. Ectopic ACTH production.

C. Adrenal adenoma.

D. Pituitary adenoma.

5. In an adult female patient with classic Cushing disease (caused by an adrenal adenoma), the preferred treatment is:

A. Mitotane 3 g three times a day.

B. Pasireotide 0.6 mg twice daily.

C. Resection of the adrenal tumor.

D. Mifepristone 300 mg once daily.

6. Which of the following drugs has been associated with an increased risk of serious hepatotoxicity?

A. Cabergoline

B. Metyrapone

C. Ketoconazole

D. Pasireotide

7. The majority of cases of primary aldosteronism are caused by:

A. Aldosterone-producing adenomas (APA).

B. Bilateral adrenal hyperplasia (BAH).

C. Unilateral adrenal hyperplasia.

D. Familial hyperaldosteronism (FH) type 1.

8. The combination of resistant hypertension, normokalemia, an aldosterone-to-renin ratio (ARR) of 23 ng/dL per ng/(mL·h) (640 pmol/L per mcg/(L·h), plasma aldosterone concentration (PAC) of 19 ng/dL (530 pmol/L), a positive fludrocortisone suppression test, a normal CT, and no lateralization on AVS would be suggestive of:

A. Bilateral adrenal hyperplasia.

B. Aldosterone-producing adenoma.

C. Licorice ingestion.

D. Familial hyperaldosteronism (FH) type 2.

9. The treatment of choice for bilateral adrenal hyperplasia-dependent aldosteronism is:

A. Spironolactone.

B. Mifepristone.

C. Angiotensin receptor blockers.

D. Partial adrenalectomy.

10. Which of the following signs or symptoms is seen in both primary and secondary adrenal insufficiency?

A. Hyperpigmentation

B. Normal aldosterone secretion

C. Normal response to the rapid ACTH stimulation test

D. Weakness

11. The agent of choice for the immediate treatment of acute adrenal insufficiency is:

A. 5% dextrose in normal saline IV.

B. Prednisone 5 mg by mouth.

C. Hydrocortisone 100 mg IV.

D. Fludrocortisone 0.1 mg by mouth.

12. Congenital adrenal hyperplasia (CAH) associated with deficiency in 21-hydroxylase can lead to selective hypoaldosteronism manifesting hyponatremia or hyperkalemia. Which of the following treatment options is preferred for selective hypoaldosteronism?

A. Mitotane

B. Spironolactone

C. Prednisolone

D. Fludrocortisone

13. Which of the following pharmacologic agents would be first line for treatment of hirsutism in women due to adrenal androgen excess?

A. Dexamethasone

B. Ethinyl estradiol and norethindrone

C. Osilodrostat

D. Gonadotropin-releasing hormone

14. When tapering long-term steroid therapy, at which of the following steroid doses should the taper be slowed and the HPA axis integrity assessed?

A. Dexamethasone 6 mg/day

B. Prednisone 20 mg/day

C. Cortisone 200 mg/day

D. Hydrocortisone 40 mg/day

15. Adult patients who will be taking long-term glucocorticoids should be warned about which of the following?

A. Weight loss and hypersomnia early in therapy

B. Osteoporosis and glaucoma with chronic therapy

C. Growth suppression

D. Need for reduced glucocorticoid dosing during times of increased stress

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** The zona glomerulosa preferentially produces aldosterone owing to a lack of 17-hydroxylase activity, greater aldosterone synthase activity, and greater angiotensin II receptor expression than other adrenal cortex zones.

2. **B.** In response to a decrease in circulating glucocorticoid concentrations, the median eminence of the hypothalamus releases corticotropin-releasing hormone which stimulates adrenocorticotropic hormone from the pituitary gland. As glucocorticoid concentrations increase, a negative feedback loop decreases the release of corticotropin-releasing hormone from the hypothalamus and adrenocorticotropic hormone from the pituitary gland.

3. **D.** Approximately 85% of ACTH-dependent Cushing syndromes are caused by pituitary adenomas.

4. **B.** Abnormal cortisol concentrations, no suppression of cortisol from low-dose DST, elevated concentrations of ACTH, normal pituitary MRI, and no gradient on IPSS favor an ectopic production etiology. See Fig. 97-4.

5. **C.** Surgical resection of offending tumors is the treatment of choice for Cushing disease. Generally pharmacotherapy is reserved as second-line

therapy in patients awaiting surgery or as adjunctive to surgery as the pharmacologic agents are associated with limited efficacy and significant side effects.

6. **C.** Ketoconazole has been associated with serious hepatotoxicity, leading regulatory authorities to restrict ketoconazole use in certain types of fungal infections (in the United States) or to remove oral ketoconazole from the market altogether (in Europe).

7. **B.** Bilateral adrenal hyperplasia causes approximately 65% of primary aldosteronism cases. The next most common etiology, aldosterone-producing adenomas, causes approximately 30% of primary aldosteronism cases.

8. **A.** Hypertension with hypo or normokalemia, ARR ≥20 ng/dL per ng/(mL·h) (550 pmol/L per mcg/(L·h)), PAC ≥15 ng/dL (420 pmol/L), unsuppressed aldosterone with a fludrocortisone suppression test, normal CT, and no lateralization on AVS would indicate bilateral adrenal hyperplasia type primary aldosteronism. For diagnosis, FH type 2 would require genetic testing and licorice ingestion would require a relevant diet history and a low PAC.

9. **A.** An aldosterone receptor antagonist is the treatment of choice for bilateral adrenal hyperplasia. Spironolactone, a nonselective aldosterone receptor antagonist, competes with aldosterone for binding at aldosterone receptors which prevent downstream effects of aldosterone receptor activity.

10. **D.** Primary adrenal insufficiency generally presents with excess ACTH causing hyperpigmentation and is associated with an abnormal response to ACTH due to decreased aldosterone secretion. Conversely, secondary adrenal insufficiency is characterized by normal aldosterone secretion and a normal response to the ACTH test, but with decreased baseline ACTH that presents can present with hypopigmentation. Both are associated with weakness.

11. **C.** Hydrocortisone is used as initial therapy for adrenal crisis as it has combined glucocorticoid and mineralocorticoid activity. If hyperkalemia persists during hydrocortisone maintenance of adrenal insufficiency, additional mineralocorticoid supplementation can be added utilizing fludrocortisone.

12. **D.** 21-hydroxylase deficiency reduces synthesis of glucocorticoids and mineralocorticoids. Selective hypoaldosteronism is associated with insufficient aldosterone levels due to a defect in stimulation of adrenal aldosterone secretion. Therefore, appropriate medical management includes exogenous mineralocorticoids (eg, fludrocortisone).

13. **B.** Oral contraceptives (eg, ethinyl estradiol and norethindrone) are the treatment of choice in most women with hirsutism. Dexamethasone and gonadotropin-releasing hormone are alternatives to oral contraceptives but are associated with increased side effects and limited efficacy.

14. **D.** A steroid taper should be slowed, and HPA axis integrity assessed, when the steroid dose approaches the equivalent of 20 to 30 mg of cortisol. Of the options, only hydrocortisone (cortisol) 40 mg/day is near this average amount, whereas the other glucocorticoid doses are much greater than physiologic doses of cortisol and it can be assumed that these doses are suppressing the HPA axis.

15. **B.** Osteoporosis and glaucoma are associated with long-term glucocorticoid therapy, especially when used at supraphysiologic doses. Weight gain and insomnia can also occur. Growth suppression is a concern in pediatric patients, but not typically adults. Generally, patients who have decreased ability to produce glucocorticoids will not be able to increase glucocorticoid production in response to increased stress. Therefore, patients with increased stress should be administered an increased dose of glucocorticoid rather than a decreased dose.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 99: Pregnancy and Lactation

Alicia B. Forinash; Kylie Barnes

KEY CONCEPTS

KEY CONCEPTS

① Complex physiology surrounds the process of fertilization and pregnancy progression.

② Medication characteristics and physiologic changes modify pharmacokinetics during pregnancy, including changes in absorption, protein binding, distribution, and elimination, requiring individualized pharmacotherapy selection and dosing.

③ Although medication-induced teratogenicity is a serious concern during pregnancy, most medications can be used during pregnancy. Healthcare providers need to evaluate the risk of the medication with the risk of the untreated condition. Informed selection of pharmacotherapy is essential.

④ Healthcare practitioners must know where to find and how to evaluate evidence related to medications used during pregnancy and lactation.

⑤ Acute pregnancy issues, such as nausea and vomiting, can be treated with nonpharmacologic treatment or carefully selected pharmacotherapy.

⑥ Some acute and chronic illnesses pose additional risks during pregnancy, requiring treatment with appropriately selected and monitored pharmacotherapies to minimize risk to the fetus and pregnant individual.

⑦ Management of the pregnant individuals during the peripartum period not only can encompass uncomplicated pregnancies/deliveries, but can also include a wide variety of potential complications that require use of evidence-based treatments to maximize positive outcomes.

⑧ Understanding the physiology of lactation and pharmacokinetic factors affecting medication distribution, metabolism, and elimination can assist the clinician in selecting appropriate medications during lactation.

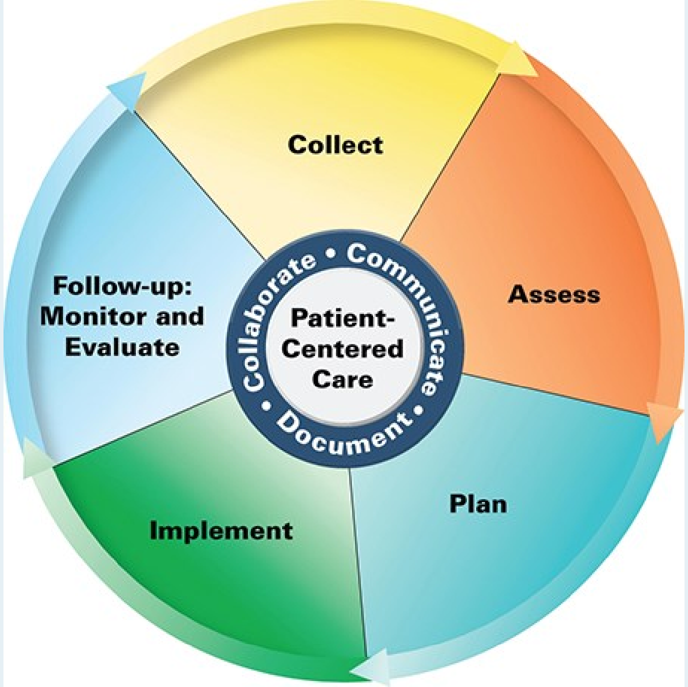
BEYOND THE BOOK

BEYOND THE BOOK

Search the Food and Drug Administration (FDA) Website (https://tinyurl.com/2ujhjm) for “Pregnancy and Lactation Labeling Rule.” Choose one link to review and then summarize the key points about the new pregnancy and lactation labeling requirements. How do they differ from pregnancy categories? Do pregnancy categories still exist? This activity is useful to enhance understanding about what type of pregnancy and lactation information to expect in medication product labeling.

PATIENT CARE PROCESS

Patient Care Process for the Management of Gestational Diabetes



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race, gender identity, biological sex, pregnancy status)
- Characteristics of the pregnancy (eg, gestational age, gravidity and parity, weight gain to date)
- Characteristics of previous pregnancy(ies) (eg, prior gestational diabetes, birth weight of previous children, unexplained fetal demise)
- Patient history (past medical, family, social habits, physical activity habits, and dietary discretion)
- Current medications (including complementary or alternative therapies) and adherence to medication schedules
- Social and cultural issues: preferences, values, and beliefs; health literacy
- Physical exam: height, weight, body mass index (BMI), blood pressure, heart rate
- Labs (urine dipstick results for glucose, protein, and albumin)

Assess*

- Risk factors and need for early screening and diagnosis (see Table 99-2)
- Screening and diagnostic testing between 24 and 28 weeks gestation for all; first trimester testing for high-risk patients (see Table 99-2)
- Achievement of target fasting and 1- or 2-hour postprandial glucose goals
- Efficacy and adherence to dietary modifications and current antihyperglycemic regimen and alternative therapies
- Achievement of goals for comorbidities (eg, blood pressure)
- Assess for depression, anxiety regarding treatment, dietary habits

- Screen for psychosocial problems and barriers to diabetes self-management

Plan*

- Set appropriate blood glucose goals based on age, comorbidities, and other factors
- Tailored lifestyle modifications (eg, diet, exercise)
- Medication therapy regimen including specific antihyperglycemic agent(s), dose, route, frequency, and duration
- Monitoring parameters including efficacy (eg, self-monitored blood glucose), safety (medication-specific adverse events, hypoglycemia), and timeframe
- Patient education (eg, potential paternal and fetal adverse events, self-monitoring parameters, risks of uncontrolled blood glucose levels, purpose of treatment, medication administration, dietary and lifestyle modifications)
- Encourage screening at 4-12 weeks postpartum visit and periodically throughout life.
- Encourage follow-up with primary care provider postpartum if not already established for continued care

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence to the treatment plan
- Schedule follow-up clinic visits to adjust the treatment plan and monitor and evaluate adverse effects

*Collaborate with patient, caregivers, and other healthcare professionals.

INTRODUCTION

As medication use in pregnancy and lactation is a controversial and emotionally charged subject, due to medicolegal and ethical implications, it is often a topic underemphasized in the education of health professionals. However, clinicians are responsible for ensuring appropriate therapy before conception, during pregnancy and parturition, and after delivery. Optimal treatments of illnesses during pregnancy sometimes differ from those used in the nonpregnant patient, and active patient participation in this process is essential.

In many cases, medication dosing recommendations for acute or chronic illnesses in pregnant individuals are the same as for the general population. However, some cases require different dosing and selection of medications. Principles of medication use during lactation, although similar, are not the same as those applicable during pregnancy.

Within this chapter, the text has been written to reduce the use of gendered terms to be more inclusive to transgender individuals as recommended by the American College of Obstetricians and Gynecologists (ACOG) and International Lactation Consultants Association (ILCA). Thus, all included gendered terms refer to biological sex and not gender.

PHYSIOLOGY OF PREGNANCY

① Fertilization and progression of pregnancy are complex, resulting in survival of only approximately 40% to 50% of embryos.[1] Because most losses occur early, usually in the first 2 weeks after fertilization, many individuals do not realize they were pregnant. Spontaneous loss of pregnancy later in gestation (ie, after 12 weeks) accounts for less than 20% of miscarriages.[2]

Fertilization occurs when a sperm attaches to the outer protein layer of the egg, the zona pellucida, and renders the egg nonresponsive to other sperm.[3] The attached sperm releases enzymes that allow the sperm to fully penetrate the zona pellucida and contact the egg's cell membrane. The membranes of the sperm and egg then combine to create a new, single cell called a *zygote*. Male and female chromosomes join in the zygote, fuse to create a single nucleus, and organize for cell division.[2,3]

Fertilization usually occurs in the fallopian tube. The fertilized egg travels down the fallopian tube over 3 to 4 days, with cell division taking place and by day 3, it reaches the uterus. Cell division continues for another 2 to 3 days in the uterine cavity before implantation. Approximately 6 days after fertilization, the cell mass is termed a *blastocyst*. Implantation begins with the blastocyst sloughing the zona pellucida to rest directly on the endometrium, allowing initiation of growth into the endometrial wall. Human chorionic gonadotropin (hCG) becomes detectable in serum or urine by pregnancy testing, as early as 8 or 9 days after ovulation; however, sensitivity may vary by brand of test.[2] By day 10 postfertilization, the blastocyst is implanted under the endometrial surface and receives nutrition from pregnant individual's blood. On the first day of the third week postfertilization, it is called an *embryo*.[4,5]

After the embryonic period (between weeks 2 and 8 postfertilization), the embryo is renamed a *fetus*. Most body structures are formed during the embryonic period, and they continue to grow and mature during the fetal period. The fetal period continues until the pregnancy reaches term, approximately 40 weeks after the last menstrual period.[5]

Gravidity is the number of times that an individual has been pregnant. A multiple birth is counted as a single pregnancy. *Parity* refers to the number of pregnancies exceeding 20 weeks of gestation and relates information regarding the outcome of each pregnancy. Medical terminology abbreviations are used to indicate an individual's gravidity (G) and parity (P) history. In sequence, the numbers reflect (a) term deliveries, (b) premature deliveries, (c) aborted pregnancies, and (d) number of living children.[2,6] For example, in an individual who has been pregnant four times and has experienced two term deliveries, one premature delivery, one ectopic pregnancy and has three living children their designation would be G_4P_{2113}.

Characteristics of Pregnancy

Pregnancy lasts approximately 280 days (about 40 weeks or 9 months) with the time period being measured from the first day of the last menstrual period to birth. *Gestational age* refers to the age of the embryo or fetus beginning with the first day of the last menstrual period, which is about 2 weeks prior to fertilization.[2] For remainder of the chapter pregnancy information will be described in gestational age. When calculating the estimated due date, add 7 days to the first day of the last menstrual period then subtract 3 months. Pregnancy is divided into three periods of 3 calendar months, each being called a *trimester*.[2] The first trimester occurs between gestational weeks 1 and 13, the second trimester weeks 14 through 27, and the third trimester weeks 28 to 40, or delivery.

Early symptoms of pregnancy include fatigue and increased frequency of urination. After the first or second missed menstrual period, nausea and vomiting can occur. While commonly called *morning sickness*, this is a misnomer as it can happen at any time of the day; however, it usually resolves at 14 to 16 weeks of gestation. Pregnant individuals may begin to feel fetal movements in the lower abdomen as early as 13 to 16 weeks gestation, with most individuals feeling movement by 18 to 20 weeks gestation.[7] Signs of pregnancy include cessation of menses, change in cervical mucus consistency, bluish discoloration of the vaginal mucosa, increased skin pigmentation, and anatomic breast changes.[2,6]

Pharmacokinetic Changes During Pregnancy

② Normal physiologic changes that occur during pregnancy may alter medication effects, resulting in the need to more closely monitor and, sometimes, adjust therapy. Physiologic changes begin in the first trimester and peak during the second trimester. For medications that can be monitored by blood or serum concentration measurements, monitoring should occur throughout pregnancy due to the many changes that occur during this time.

During pregnancy, a pregnant individual's plasma volume, cardiac output, and glomerular filtration each increase (50%, 30%-50%, and 50%-80%, respectively), potentially lowering the concentration of renally eliminated medications.[8] With changes in plasma volume and body weight, the volume of distribution of medications may be affected. Plasma albumin concentration decreases, which increases the volume of distribution of medications that are highly protein bound. However, unbound medications are more rapidly cleared by the liver and kidney during pregnancy, resulting in little change in concentration. Hepatic perfusion also increases, which could theoretically increase the hepatic extraction of medications; activity of metabolic enzymes and drug transporters changes during pregnancy. Activity of cytochrome P450 3A4, 2C9, and 2D6, as well as UGT1A4 are increased while that of 1A2 is decreased.[9,10] Nausea and vomiting, as well as delayed gastric emptying, may also alter the absorption of medications.

Transplacental Medication Transfer

② Although once thought to be a barrier to medication transfer, the placenta is the organ of exchange between the pregnant individual and fetus for a number of substances, including medications.[12] Most move from the pregnant individual's circulation to the fetal circulation by diffusion.[14] Certain chemical properties impact transplacental medication transfer, such as half-life, lipid solubility, electrical charge, molecular weight, and degree of protein binding of medications. Providers prefer medications with a high molecular weight, shorter half-life, high protein binding, as medications with these properties have a lower potential to cross the placenta.[13,14]

Medications with molecular weight less than 500 Da readily cross the placenta, whereas larger molecules (600-1,000 Da) cross more slowly.[14] Medications with molecular weight greater than 1,000 Da, such as insulin and heparin, usually do not cross the placenta in significant amounts. Lipophilic medications, such as opioids and antibiotics, cross the placenta more easily than do water-soluble medications. A pregnant individual's plasma albumin progressively decreases, which may result in higher concentrations of certain protein-bound medications in the fetus. Fetal pH is slightly more acidic than pregnant individual's pH.[14,15] Once in the fetal circulation, weak bases (eg, bupivicaine) become more ionized leading to ion trapping, higher fetal levels, and are less likely to diffuse back into the pregnant individual's circulation.[14,15]

PHARMACOTHERAPY SELECTION DURING PREGNANCY

③ Many misconceptions exist regarding the association of medications and birth defects. Although some have the potential to cause teratogenic effects, most required by pregnant individuals can be used.

The baseline risk (also known as background risk) for congenital malformations is approximately 3% to 5%.[16] It is imperative when selecting medications to compare the baseline risk to the potential risk of medication exposure. Medication exposure is estimated to account for less than 1% of all birth defects; instead 80% are related to unknown causes, 15% chromosomal causes, 4% genetic causes, and less than 1% from other environmental issues (eg, a pregnant individual's conditions and infections).[2]

Factors such as the stage of pregnancy during exposure, medication route of administration, and dose can also affect outcomes.[12] In the first 4 weeks of gestation, exposure to a teratogen may result in an "all-or-none" phenomenon, which could either destroy the embryo or cause no problems.[17] Organogenesis occurs during the embryonic period when organ systems are developing; therefore, teratogenic exposures may result in structural anomalies. For the remainder of the pregnancy, exposure to teratogens may result in growth restriction, central nervous system (CNS) abnormalities, impaired organ function, and fetal demise. Examples of medications associated with teratogenic effects in the period of organogenesis include some chemotherapy agents (eg, methotrexate and cyclophosphamide), some sex hormones (eg, androgens), lithium, retinoids, thalidomide, warfarin, and certain antiseizure medications. Other medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and tetracycline derivatives, are more likely to exhibit effects in the second or third trimester.[2,12]

Medications are often necessary during pregnancy for treatment of acute and chronic conditions. Identifying patterns of medication use before conception, eliminating nonessential medications and discouraging self-medication, minimizing exposure to medications known to be harmful, and adjusting doses are all strategies to optimize the pregnant individual's health while minimizing the risk to the fetus. In summary, a small number of medications have the potential to cause congenital malformations, and many can be avoided during pregnancy. In situations where a medication may be teratogenic but is necessary for the pregnant individual's care, considerations related to route of administration, dosage form, and dosing may lessen the risk.

Methods and Resources for Determining Medication Safety in Pregnancy

④ When assessing the safety of using medications during pregnancy, evaluation of the quality of the evidence is important. Ideally, safety data from randomized, controlled trials are most desirable, but pregnant individuals are not usually eligible for participation in clinical trials. Other types of data commonly used to estimate the risk associated with medication use during pregnancy include animal studies, case reports, case–control studies, prospective cohort studies, historical cohort studies, and voluntary reporting systems (eg, registries). Information can be found from the FDA (https://www.fda.gov/science-research/womens-health-research/list-pregnancy-exposure-registries) and package inserts, and patients should be encouraged to enroll in medication registries when medications are used throughout pregnancy to increase information on medication exposure.

Animal studies are a required component of medication testing, but extrapolation of the results to humans is not always valid, and 75% of the time animal medication exposure does not demonstrate a similar response in humans. Additionally relying on animal data is often limited due to species differences, issues with poor study methodology, concerns for publication bias, study or data inconsistency, and lack of clinical translation.[18] A prime example of this is thalidomide, which was regarded as safe in some animal models, but proved to have significant teratogenic effects in human offspring.[2,12] The value of case reports is limited because birth defects in the offspring of pregnant individuals who used medication during pregnancy may occur by chance.[12] It is important to also consider other factors that can influence pregnancy outcomes, such as exposure to tobacco, alcohol, recreational substances, environmental factors, and infection or uncontrolled disease states in an pregnant individual, as these factors are not always accounted for in literature and each can impact pregnancy outcomes.[2,12] Case–control studies identify an outcome (congenital anomaly), match subjects with or without that outcome, and report how often exposure to a suspected agent occurred. Recall bias is a concern, with retrospective design, as individuals with an affected pregnancy may be more likely to remember medications used during the pregnancy than those with a routine pregnancy.

Cohort studies that evaluate the intervention (use of a particular medication) in a group of persons and compare outcomes in a similar group of subjects without the intervention are also possible.[1,12] Prospective studies eliminate some of the problems with recall bias, but require time and large numbers of participants and may not adequately account for potential confounding variables. Despite these disadvantages, cohort studies are often used for evaluating the effects of medication exposure on pregnancy outcomes.

Teratology information services provide pregnant individuals and healthcare providers with information about potential exposures during pregnancy. Many also offer additional resources including patient education materials (eg, https://mothertobaby.org/fact-sheets/).[12] These services may publish pooled data to facilitate information sharing about medications used during pregnancy. Some pharmaceutical companies have organized voluntary reporting systems (also called pregnancy registries) for medications used during pregnancy.

④ Computerized databases (eg, LactMed [https://ncbi.nlm.nih.gov/books/NBK501922/), guidelines and textbooks with information regarding medication use during pregnancy and lactation offer valuable assistance.

The FDA approved product-labeling requirements for medications approved after June 20, 2015 include a subsection for pregnancy that provides information about pregnancy exposure registries, a risk summary, clinical considerations, supporting data, lactation, and if there are concerns for reproductive health. Prescription medications approved after June 30, 2001 are required to have updated product labeling to meet the new requirements and use of the new requirements have been phased in gradually. Medications approved before June 30, 2001 do not have to implement the new labeling requirements, but were required to remove the pregnancy category from product labeling. Risk categories remain in product labeling only for over-the-counter (OTC) medications, due to the multiple limitations of the pregnancy risk categories (ie, A, B, C, D, and X) previously used to guide clinicians regarding medication risk during pregnancy.[19]

In summary, determining medication safety during pregnancy is limited by the quality of data and the types of study designs that can be used. While information from product labeling may provide a rough estimate of risks for medication-related adverse fetal outcomes, careful evaluation of other available information sources is necessary to make decisions about medication use in pregnant individuals.

PRECONCEPTION PLANNING

Pregnancy outcomes are influenced by the pregnant individual's health status, lifestyle, and history prior to conception. The goal of preconception care is health promotion, through modification of behavioral, biomedical, and social risks in all individuals of reproductive age able to become pregnant, to ensure optimal health and improve pregnancy outcomes.[20] Almost half of all pregnancies in the United States are unintended. Preconception planning is important, since some behaviors and exposures impart risk to the fetus during the first trimester, often before prenatal care is begun or even before pregnancy is detected. Table 99-1 lists selected preconception risk factors, the potential adverse pregnancy outcomes, and management or prevention options.

TABLE 99-1

Selected Preconception Risk Factors for Adverse Pregnancy Outcomes

Preconception Risk Factor	Potential Adverse Pregnancy Outcomes	Management or Prevention Options
Use of known teratogens		
• Antiseizure Medications	• Some are known teratogens; causes craniofacial, cardiac, and limb defects[a] • NTD • Fetal hydantoin syndrome	• Optimize to lower risk therapy while maintaining control prior to conception • Avoid valproic acid use monotherapy if possible • Start folic acid at least 0.4 mg daily preferably at least 3 months prior to conception
• Retinoids	• Spontaneous abortion • Known teratogen; causes CNS, craniofacial, and cardiac defects[a]	• Discontinue at least 1 month (isotretinoin, bexarotene) or 3 years (acitretin) before attempting conception • Enrolled in iPLEDGE (isotretinoin), Education and Pregnancy Prevention for Acitretin (EPPA) or Do Your P.A.R.T. (acitretin). Follow manufacturer recommendations for contraception (isotretinoin, acitretin, bexarotene)
• Warfarin	• Fetal warfarin syndrome	• Switch to nonteratogenic anticoagulant (eg, LMWH) before becoming pregnant • Patients with mechanical valves may remain on warfarin for some or all of the pregnancy
Lifestyle factors		
• Alcohol use	• Fetal alcohol syndrome	• Cease alcohol intake before conception
• Obesity	• Malformations (eg, NTD and orofacial) • Preterm delivery • Spontaneous abortion • Stillbirth • Macrosomia • Impaired growth • Cesarean section	• Weight loss with appropriate nutritional intake before pregnancy
• Tobacco use	• Preterm birth • Low birth weight • Spontaneous abortion • Increased perinatal mortality • Orofacial clefts • Intrauterine growth	• Ideally, cease tobacco use before conception • Individualize approach with nonpharmacologic therapies (including psychosocial and behavioral interventions like CBT, motivational interviewing, and counseling) and can consider NRT products, bupropion, varenicline. Discuss risks and benefits with the patient

	restriction - Sudden infant death syndrome	
- Cannabis use	- Intrauterine fetal demise - Low birth rate[b] - Preterm delivery[b]	- Ask about medical and nonmedical use of marijuana in all patients - Educate about potential risks - Encourage to discontinue use ideally prior to conception

[a]List is not all-inclusive

[b]When stratified by frequency of use (risk at least weekly use)

CBT, cognitive behavioral therapy; CNS, central nervous system; HTN, hypertension; NRT, nicotine replacement therapy; NTD, neural tube defect; VTE, venous thromboembolism.

Data from References 2-12,21-32.

The most common major congenital abnormalities are neural tube defects (NTDs), cleft palate and lip, and cardiac anomalies. Each year in the United States approximately 3,000 pregnancies are affected by a NTD.[22,33] Folic acid supplementation in individuals of childbearing potential substantially reduces the incidence of NTDs in their offspring. This is also true in individuals who have previously delivered babies with NTDs, as they occur within the first month of conception due to neural tube closure occurring by gestational week 6. Folic acid supplementation of at least 0.4 mg daily is recommended throughout the reproductive years, since many pregnancies are unplanned and may not be recognized until after the first month.[22,34] Additionally, 4 mg of folic acid per day starting 3 months prior to conception and continued until 12 weeks gestation is recommended for individuals at high risk for neural tube defects, which includes those with a personal, partner, or previous pregnancy history of neural tube defects.[22]

Use of alcohol and substances during pregnancy is also associated with risk (see Table 99-1).[2,12,21–32] In 2012 in the United States, alcohol use, substance use, and cigarette use were reported in 8.5%, 5.9%, and 15.9% of pregnant individuals, respectively.[35] ACOG recommends that patients should be educated about the risks of smoking and potential risks of using nicotine replacement therapy, and patients should be closely monitored while on therapy.[31] Nicotine replacement therapy during pregnancy may help improve cessation rates and theoretically imparts less risk than exposure to the over 4,000 chemicals found in cigarettes.[31,36] Although bupropion is not associated with risk during pregnancy, a Cochrane review found that bupropion did not improve cessation rates in pregnancy.[31,36] Varenicline has limited safety and efficacy data in pregnancy, but available data has not demonstrated teratogenic effects.[36]

ACUTE PREGNANCY ISSUES

Pregnancy causes or exacerbates conditions that pregnant individuals commonly experience, including nausea and vomiting, constipation, hemorrhoids, and gastroesophageal reflux. Individuals with pregnancy-influenced gastrointestinal (GI) issues can be treated with lifestyle modification or medications, many of them are nonprescription.

Nausea and Vomiting

⑤ Nausea and vomiting of pregnancy (NVP) impacts 50% to 80% of pregnant individuals.[37] NVP usually begins between weeks 4 and 6 of gestation and usually resolves by weeks 14 to 16 with peak symptoms occurring between weeks 8 and 12.[2,11] Hyperemesis gravidarum (HG; ie, unrelenting vomiting causing weight loss of more than 5% prepregnancy weight, dehydration, electrolyte imbalance, and ketonuria) occurs in 0.3% to 3% of pregnant individuals.[2,11,37] Healthcare providers should educate patients with NVP on nonpharmacological interventions. Dietary modifications, such as eating frequent, small, bland or dry meals every 1 to 2 hours, consuming crackers before getting out of bed in the morning, snacking on high-protein foods, and eliminating fatty or spicy foods, may be helpful. Applying pressure at acupressure point P6 on the volar aspect of the wrist (between the two tendons on about three fingers below the wrist) may be beneficial. Avoiding triggers such as odor, heat, humidity, noise, and flickering lights may help.[11,37] Additionally, ACOG recommends ginger 250 mg capsules four times daily. If pharmacologic therapy is needed, ACOG recommends pyridoxine 10 to 25 mg with or without doxylamine 12.5 mg up to four times daily, depending on the formulation selected, as the first-line therapy.[37] Immediate release tablets for both agents are available over the counter; however, adverse events such as sedation with doxylamine may limit use. Both extended and delayed release combination tablets are available by prescription, but cost may limit use. If symptoms persist, second line add on therapies include dimenhydrinate, diphenhydramine, prochlorperazine, and promethazine. Both prochlorperazine and promethazine are available as suppositories if patients are struggling to keep oral products down. For continued symptoms in patients without dehydration, recommended therapies include metoclopramide, ondansetron, and trimethobenzamide as third-line agents.[37] Although metoclopramide has not been associated for a risk of malformations, it carries a boxed warning for tardive dyskinesia.[37,38] Additionally, combination of dopamine antagonist therapies such as metoclopramide and phenothiazines may also increase the risk for extrapyramidal symptoms.[37] Conflicting data exist regarding ondansetron use and the risk for malformations such as cardiovascular defects and oral clefts.[26,37] Ondansetron use prior to 10 weeks gestation should be individualized by patient, after careful consideration of the associated risks and benefits. Additionally, ondansetron use may prolong the QT interval, particularly in patients with underlying cardiac issues, personal or family history of QT prolongation, use with other medications that can prolong the QT, or electrolyte imbalances. In patients with dehydration, intravenous fluids should be administered, and providers consider intravenous therapy with dimenhydrinate, metoclopramide, ondansetron, or promethazine. Intravenous or intramuscular chlorpromazine or methylprednisolone may be added on for patients with persistent symptoms. Corticosteroids may be effective for HG; use should be reserved until after 10 weeks gestation due to a small increase in the risk of oral clefts.[37]

Constipation and Hemorrhoids

⑤ Constipation during pregnancy is prevalent, affecting almost 40% of individuals and may contribute to the development or exacerbation of hemorrhoids which are more prevalent in pregnant persons compared with the general population.[11] Nonpharmacologic treatment (ie, high dietary fiber intake, maintaining hydration by increasing water intake, and use of sitz baths) or moderate physical activity should be recommended alone or in combination with medication therapy. Bulk-forming agents (eg, psyllium, methylcellulose, and polycarbophil) are considered appropriate for long-term use because they are not absorbed or associated with an increased risk of malformations. However, they are not always effective, can take several days to work, and can be associated with unpleasant adverse effects including gas, bloating, and cramping. In addition, bulk-forming agents may lack palatability, especially for patients struggling with nausea and vomiting throughout pregnancy. Osmotic laxatives, specifically polyethylene glycol, are commonly utilized throughout pregnancy. Their use has not been associated with adverse effects in pregnancy; however, the patient might experience adverse effects such as bloating and increased flatulence. Polyethylene glycol is the preferred medication for patients with chronic constipation during pregnancy. In addition, stool softeners (eg, docusate) may be also be used and are well tolerated.[11] Stimulant laxatives (ie, senna and bisacodyl) are associated with a fast onset of action, however should be reserved for short-term use. If utilized long-term, use should be limited to 3 days per week.[39] Use of magnesium should be cautioned, as can lead to dehydration secondary to diarrhea, and long-term use may lead to magnesium toxicity. In addition, magnesium may increase the risk for electrolyte imbalances. Castor oil and mineral oil should be avoided because they may cause stimulation of uterine contractions and impairment of fat-soluble vitamin absorption, respectively.[11,26] Data supporting other management options for hemorrhoids during pregnancy are limited. Topical anesthetics, skin protectants, and astringents (eg, witch hazel) can be used for anal irritation and pain. Hydrocortisone may reduce inflammation and pruritis.[40]

Gastroesophageal Reflux Disease

⑤ Up to 80% of individuals experience gastroesophageal reflux disease during pregnancy.[41] Nonpharmacologic therapy with lifestyle and dietary modifications can be recommended alone or with medication therapy (see Chapter 50, “Gastroesophageal Reflux Disease”). Antacids (eg, aluminum, calcium, magnesium preparations) are commonly used to relieve symptoms. Magnesium trisilicate-based antacids (eg, Gaviscon®) are less preferred because when used in high doses or long-term have been associated with nephrolithiasis, hypotonia, cardiovascular impairment and respiratory disease in the fetus. In addition, sodium bicarbonate-based antacids (eg, Alka-Seltzer®) are generally not recommended in pregnancy due to risk for fluid overload and metabolic alkalosis.[41] Additionally, sucralfate is used along with lifestyle modifications because it has minimal systemic absorption.[39] Histamine-2 receptor antagonist (H_2RAs), most commonly famotidine, can be used for patients unresponsive to lifestyle changes and antacids or sucralfate. Twice daily dosing with H_2RA therapy is commonly used in pregnancy. The use of proton pump inhibitors (PPIs) during pregnancy are generally reserved for patients who fail H_2RA therapy or who required a PPI prior to pregnancy. PPI therapy does not appear to increase the risk of major birth defects; however, most data comes from use of omeprazole.[11,26] Despite previous concerns regarding omeprazole use during pregnancy, a large cohort study evaluating PPI use during pregnancy did not show an increased risk of birth defects in females who took PPIs, including omeprazole.[42] In instances where delayed gastric emptying is contributing to reflux symptoms, metoclopramide may be considered as an add on therapy to an H_2RA or PPI.

Diabetes in Pregnancy

⑥ Up to 7% of pregnancies are complicated by any type of diabetes, with gestational diabetes mellitus (GDM) accounting for roughly 86% of cases overall.[44] Diabetes diagnosed prior to pregnancy is commonly referred to as pregestational diabetes, whereas GDM is most commonly diagnosed between 24 to 28 weeks gestation. GDM is a complex condition characterized by the development of carbohydrate intolerance, pancreatic β-cell dysfunction, and insulin resistance that occurs during pregnancy. Diabetes that develops during the first trimester of pregnancy is most commonly type 2 diabetes that has been previously undiagnosed; however, this condition may be type 1 diabetes or GDM. The most common risk factor for developing GDM is a history of GDM in a previous pregnancy. Additional risk factors include: high-risk race (Asian American, American Indian, Pacific Islander, African American, and Latinx populations), BMI greater than or equal to 25 kg/m^2 (or greater than or equal to 23 kg/m^2 for Asian individuals), history of diabetes in a first-degree relative, previous birth of an infant weighing 4,000 g (about 9 pounds) or more, physical inactivity, hypertension or on medication for hypertension, polycystic ovary syndrome, high-density lipoprotein cholesterol less than 35 mg/dL (0.91 mmol/L), triglycerides greater than 250 mg/dL (2.83 mmol/L), A1c greater than 5.7% (0.057; 39 mmol/mol) or impaired fasting glucose on previous testing, other clinical indications of insulin resistance such as prepregnancy BMI greater than 40 kg/m^2 or acanthosis nigricans, and history of cardiovascular disease.[43,44]

Complications During Pregnancy

Poorly controlled diabetes, regardless of type, can increase the risk for fetal malformations, fetal morbidity and mortality, and morbidity for the pregnant individual. The most common fetal complications include macrosomia (birthweight greater than 4,000 g), neonatal hypoglycemia often requiring neonatal intensive care unit stay, hyperbilirubinemia, and birth trauma.[45] In individuals with pregestational diabetes, preconception A1c plays an important role in determining risk for fetal malformations. Patients with a preconception A1c between 5% to 6% (0.05-0.06; or 31-42 mmol/mol) have a fetal malformation rate similar to pregnancies not impacted by diabetes. As a patient's preconception A1c approaches 10% (0.1; 86 mmol/mol) and higher, the fetal malformation rate increases to 20% to 25%. The most commonly observed malformations include cardiac defects, CNS anomalies, and skeletal malformations.[46] An increased risk for long-term complications also exist for the child, and include impaired glucose tolerance, type 2 diabetes, hypertension, obesity, and hyperlipidemia. Risk to the pregnant individual include higher incidence of cesarean delivery, hypertension and preeclampsia, metabolic syndrome, and cardiovascular disease. In addition, individuals with GDM are at a 10-fold increased risk for developing type 2 diabetes later in life, and those with pregestational diabetes are at risk for worsening retinopathy and deteriorating renal function.[43,47]

Screening and Diagnostic Criteria

Due to the risks for both the pregnant individual, fetus, and neonate, the American Diabetes Association (ADA) and American College of Obstetricians and Gynecologists (ACOG) recommend universal screening for GDM in all patients not previously diagnosed with type 1 or 2 diabetes between 24 to 28 weeks' gestation. Individuals considered at an increased risk for GDM as defined previously should be screened in early pregnancy. Generally, screening is recommended at the first pregnancy visit for those at high risk if the patient is able to tolerate screening; however, screening may be delayed in patients with uncontrolled nausea or vomiting. If GDM is not diagnosed with early screening, screening should be completed again between 24 and 28 weeks' gestation.[44] A diagnosis of GDM can be confirmed using two different approaches: a one-step strategy or a two-step strategy (Table 99-2).

TABLE 99-2

Screening and Diagnosis of Gestational Diabetes Mellitus

One-Step Method	
Complete a 75-g oral glucose tolerance test. Plasma glucose is assessed at fasting, and after 1 and 2 hours. The test should be performed in the morning following an overnight fast of at least 8 hours.	• GDM diagnosis is confirmed when one or more of the plasma glucose levels are met or exceeded: • Fasting: 92 mg/dL (5.1 mmol/L) • 1 hour: 180 mg/dL (10.0 mmol/L) • 2 hour: 153 mg/dL (8.5 mmol/L)
Two-Step Method	
Step 1: Complete a 50-g oral glucose loading test. This is typically done in a non-fasting state. Plasma glucose is assessed after 1 hour.	If the plasma glucose level is greater than or equal to 140 mg/dL[a](7.8 mmol/L), the patient moves to step 2.
Step 2: Complete a 100-g oral glucose tolerance test. Plasma glucose is assessed at fasting, after 1, 2, and 3 hours.	• GDM diagnosis is confirmed when at least two of the following plasma glucose levels are met or exceeded: • Fasting: 95 mg/dL (5.3 mmol/L) • 1 hour: 180 mg/dL (10 mmol/L) • 2 hour: 155 mg/dL (8.6 mmol/L) • 3 hour: 140 mg/dL (7.8 mmol/L)

[a] A lower threshold of 130 or 135 mg/dL (7.2 or 7.5 mmol/L) may be utilized by some providers; ADA recommends 140 mg/dL (7.8 mmol/L)

Data from References 43,44.

Glucose Monitoring

Daily self-monitoring of blood glucose is recommended for all persons with diabetes during pregnancy, including those with GDM. Evidence supporting optimal frequency of glucose monitoring is lacking; however, in general, patients are recommended to test at least four times daily, with some testing up to seven times a day. Common testing times include fasting glucose, one or two hours after each meal, and before bedtime, with postprandial glucose levels being the best indicator of risk of macrosomia and other complications during pregnancy. Additional testing times are commonly recommended for the following scenarios: premeal glucose monitoring in patients using an insulin pump or if insulin doses are based on premeal values, and between 2 and 3 am if nocturnal hypoglycemia is suspected. Regular A1c monitoring is considered a secondary measure of glycemic control during pregnancy and is not routinely utilized for guiding glucose management, however may still be assessed once a trimester. Of note, A1c levels decrease by as much as 0.5% (0.006; 0.6 mmol/mol)(during normal pregnancy due to an increase in red blood cell turnover. An A1c target of less than 6% (0.06; 42 mmol/mol) is optimal during pregnancy as it is associated with the lowest risk of large for gestational age infants, preterm delivery, and preeclampsia.[43,44]

Glycemic control can change dramatically during pregnancy and frequent adjustments to management are often needed. Medical nutrition therapy, exercise, and blood glucose monitoring are considered first-line therapies for all with GDM, and as many as 70% to 85% of patients can achieve control with these interventions.[43] Dietary and exercise interventions should be recommended for all patients, but plans are individualized. Refer to the guidelines for specific recommendations.[43,44,46]

Glucose Management

Pharmacotherapy should be initiated when medical nutrition therapy and exercise fail to achieve glucose goals within 1 to 2 weeks after initiation.[44] The general threshold that triggers the need for pharmacologic therapy has not been well established; however, many providers will start therapy if most of the glucose concentrations within the most recent week are elevated above goal. The current ACOG guidelines recommend starting insulin under the following parameters: fasting glucose concentrations consistently greater than 95 mg/dL (5.3 mmol/L), 1-hour postprandial concentrations consistently greater than 140 mg/dL (7.8 mmol/L), or 2-hour postprandial concentrations consistently greater than 120 mg/dL (6.7 mmol/L).[44] Insulin is the recommended first line when medication therapy is needed. If patient refuses insulin or has financial limitations, language barriers, or the provider has significant concerns for routine patient follow-up, oral therapy with metformin or glyburide may be considered.[43,44]

Insulin

Both ACOG and ADA recommend insulin as first-line therapy for glucose management during pregnancy. Human insulin does not cross the placenta whereas animal insulins can cross in insignificant amounts.[26,43] A preferred insulin regimen during pregnancy has not been established.[48] Basal insulin options include insulin NPH, insulin glargine, and insulin detemir. The initial studies of glucose management in GDM used insulin NPH, thus it is the standard to which all other insulins are compared. Insulin glargine and detemir are the most commonly used long-acting insulins for basal insulin coverage during pregnancy.[49,50] Data regarding insulin degludec during pregnancy are limited, although pregnancy outcomes appear to be similar to outcomes with other insulin regimens.[51]

Bolus insulin options include insulin lispro and insulin aspart and both do not cross the placenta and are commonly used during pregnancy. Either insulin lispro or insulin aspart should be used primarily over regular insulin because they are associated with a quicker onset of action which helps prevent hypoglycemia and insulin dosing errors. Data regarding insulin glulisine during pregnancy are limited; however, information available has not shown an increased risk for adverse pregnancy outcomes.[52]

Several daily injections of insulin are often needed during pregnancy to achieve optimal control. The ADA and ACOG do not specify a preferred insulin dosing approach for initiating therapy during pregnancy, nor do they prefer specific insulin. A general weight-based approach suggests starting 0.7 to 1 unit/kg/day of insulin in divided doses.[44] Due to patient variability in dietary intake and increases in insulin resistance that increases throughout pregnancy, insulin doses will likely be titrated often based on the patient's home glucose monitoring.

Metformin

Both ADA and ACOG recommend metformin as an alternative agent for lowering blood glucose during pregnancy. Metformin readily crosses the placenta and was previously used frequently during pregnancy. Metformin is associated with a lower risk of neonatal hypoglycemia and lower weight gain in pregnant individuals compared to insulin, which made it a viable oral option for glucose management during pregnancy.[53,54] Data evaluating metformin in combination with insulin during pregnancy found individuals on the combination required less insulin, gained less weight, lower incidence of macrosomia, and had fewer cesarean deliveries compared to insulin alone.[55] In addition, more than 40% of those on metformin monotherapy during pregnancy ultimately require insulin to achieve glycemic control.[44] There are concerns for long-term metabolic changes in offspring exposed to metformin during pregnancy.[56,57] The long-term metabolic impact on metformin use during pregnancy is not well established; however, there are concerns with exposure during pregnancy and additional data are needed to fully assess the long-term safety and efficacy outcomes. Individuals started on metformin during pregnancy should be educated that metformin crosses the placenta and fetal exposure could result in long-term metabolic effects into childhood.

Glyburide

Both ADA and ACOG recommend glyburide as an alternative to metformin for lowering blood glucose during pregnancy.[43,44] As a class, sulfonylureas cross the placenta; however, glyburide is the only agent used in pregnancy due to minimal crossing through the placenta. Compared to both insulin and metformin, glyburide is associated with an increased risk of infant macrosomia and neonatal hypoglycemia, even when controlling for similar levels of glycemic control.[44] Observational studies have also reported higher incidence of preeclampsia, hyperbilirubinemia, and stillbirth in patients taking glyburide compared to insulin.[43] In addition, more than 20% of those on glyburide monotherapy during pregnancy ultimately require insulin to achieve glycemia control.[43] Glyburide therapy may be less effective in patients with higher baseline fasting glucose concentrations at diagnosis, and in patients with a history of GDM in a previous pregnancy or when GDM is diagnosed before 26 weeks' gestation.[58]

Postpartum Management and Screening

Insulin resistance begins to decline rapidly postpartum immediately once the placenta is delivered, requiring close glucose monitoring and often aggressive insulin adjustments.[59] During the first one to two weeks postpartum, insulin sensitivity begins to return to prepregnancy levels. Patients with GDM can often discontinue insulin during this time, and patients with type 1 or 2 diabetes often require significant insulin adjustments. Patients should be educated about the increased risk of hypoglycemia, including how to treat hypoglycemia, especially during this time of decreased sleep and when eating schedules can be erratic. Breastfeeding should be encouraged and supported for patients with diabetes during pregnancy.

Although many individuals with GDM return to normal glycemic control shortly after delivery, patients with GDM have a 10-fold increased risk of developing type 2 diabetes in their lifetime.[43] Due to this increased risk, the ADA recommends patients diagnosed with GDM during pregnancy be screened for persistent diabetes between 4 to 12 weeks postpartum most commonly with a 2-hour oral glucose tolerance test.[43] Diagnostic criteria for diagnosing diabetes follows the nonpregnant criteria. If type 2 diabetes is not diagnosed during the postpartum period, periodic screening is recommended every 1 to 3 years with any recommended glycemic test. Lifestyle interventions with a healthier diet and lower weight, and metformin can help prevent or delay the progression to diabetes by 35% to 40%, respectively, over 10 years.[43]

Hypertensive Disorders of Pregnancy

⑥ Hypertensive disorders of pregnancy (HDP) are one of the most common causes of mortality in pregnancy, as well as perinatally. Four categories of HDP are established: (1) chronic hypertension (HTN), preexisting HTN or developing before 20 weeks gestation); (2) gestational HTN (HTN without proteinuria developing after 20 weeks of gestation); and (3) preeclampsia (HTN with proteinuria) with gestational HTN, may present as the first symptoms of HTN disorder during pregnancy; and (4) chronic HTN with superimposed preeclampsia.[60,61] Hypertension in pregnancy is defined as either systolic blood pressure (sBP) above 140 mm Hg or diastolic blood pressure (dBP) above 90 mm Hg based upon two or more measurements at least 4 hours apart.[61] Severe hypertension is diagnosed after two measurements of sBP > 160 mm Hg and/or dBP > 110 mm Hg. The two measurements can be confirmed within a short interval (minutes) in order to start antihypertensive therapy quickly.

Risk factors for development of gestational HTN include nulliparity, individuals with first degree relative with history of gestational HTN (eg, sibling or parent), non-singleton pregnancies, age less than 20 years or older than 40 years, and a history of HTN or kidney disease in a previous pregnancy.[62]

Preeclampsia is a more complex, multisystem syndrome that complicates up to 8% of pregnancies. Risk factors for development of preeclampsia are detailed in Table 99-3. Preeclampsia can be divided into early onset (prior to 34 weeks or requiring delivery prior to 37 weeks), late onset, or present up to 6 weeks postpartum. Early onset preeclampsia is typically severe in nature and associated with more morbidity for pregnant individuals. Diagnosis of preeclampsia includes elevated blood pressure as with HDP and proteinuria (>300 mg/24 hours or a protein/creatinine ratio of >300 mg/g (30 mg/mmol) are preferred, or urine dipstick of 2+). If proteinuria is not present, new onset of any of the following findings with new onset HTN is indicative of preeclampsia: thrombocytopenia (count less than 100×10^3/L [100×10^9/L]), serum creatinine above 1.1 mg/dL (97 μmol/L) or a doubling of serum creatinine, elevated liver transaminases at least twice the upper limit of normal, pulmonary edema, or new onset headache nonresponsive to analgesics or with visual symptoms.[61] Individuals may also experience chest pain or dyspnea, vomiting, and epigastric pain. Other signs and symptoms of preeclampsia that would warrant delivery include: severe uncontrolled HTN, eclampsia, persistent severe headache, pulmonary edema, placental abruption, disseminated intravascular coagulation, and HELLP syndrome (Hemolysis, Elevated Liver enzymes, Low Platelets) or evidence of adverse fetal effects, such as growth restriction.[61]

TABLE 99-3

Risk Factors for Preeclampsia

High-Risk Factors	Moderate-Risk Factors
Preeclampsia in a prior pregnancy	Nulliparity
Non-singleton pregnancy	Prepregnancy BMI greater than 30 kg/m^2
Chronic hypertension	Family history of preeclampsia (1st degree relative—parent or sibling)
Pregestational diabetes	Sociodemographic characteristics (eg, African American race, low socioeconomic status)
Renal disease	Age greater than 35 years
Autoimmune disease (eg, systemic lupus erythematosus, antiphospholipid syndrome	Medical history factors (eg, low birth weight or small for gestational age, previous adverse pregnancy outcome, more than 10-year pregnancy interval)
Combinations of multiple moderate-risk factors	

Data from References [61,66].

Preeclampsia may progress rapidly to eclampsia, which is defined by new-onset tonic-clonic, focal, or multifocal seizures superimposed on preeclampsia. Eclampsia is a medical emergency that can occur antepartum, intrapartum, or postpartum. It is often preceded by a headache, visual changes such as blurred vision or photophobia, or altered mental status; however, it may present with no warning signs or symptoms.[61,63]

Complication of Hypertension

All types of HDP are associated with risks to the fetus and pregnant individuals, with these risks increasing with uncontrolled HTN. Complications for the pregnant individual associated with HDP include preeclampsia, eclampsia, stroke, labor induction, and placental abruption. Fetal complications include intrauterine growth restriction, preterm delivery, low birth weight, and stillbirth. Additionally, chronic HTN is associated with increased risk for additional pregnancy and fetal complications including death, pulmonary edema, renal insufficiency and failure, myocardial infarction, cesarean delivery, postpartum hemorrhage, gestational diabetes, and congenital anomalies (eg, heart defects, hypospadias, esophageal atresia).[60]

Management of Hypertension

There is no consensus on treatment thresholds in individuals with mild hypertension. The ACOG recommends pharmacotherapy be initiated quickly in individuals with acute-onset severe HTN that is confirmed as persistent (lasting more than 15 minutes).[61] Due to a lack of evidence supporting the use of antihypertensive medications in patients with lower blood pressures, pharmacologic therapy is recommended once the patient has persistent blood pressures greater or equal to sBP 160 mm Hg and/or dBP 110 mm Hg. The ACOG recommends providers consider using lower blood pressure thresholds in individuals with comorbidities or underlying impaired renal function, but does not provide a specific threshold. When antihypertensive medications are used, it is recommended to maintain blood pressure levels between sBP 120 mm Hg and 160 mm Hg and dBP between 80 mm Hg and 110 mm Hg. Lowering of blood pressure should occur over a period of hours and aggressive blood pressure lowering should be avoided due to concerns for decreased uteroplacental blood flow.[60]

Treatment of Hypertension

Labetalol and nifedipine are the preferred treatment options for management of HTN during pregnancy. Labetalol is commonly used in practice; however, use may be limited in patients with asthma due to potential for bronchoconstrictive effects. It is also important to monitor the patient for bradycardia. Nifedipine extended-release is also commonly used in practice with twice daily dosing due to increased elimination. Immediate-release formulations are usually reserved for severe or acutely elevated blood pressure levels in hospitalized patients. Methyldopa is rarely used in practice due to lack of efficacy and increased adverse effects (eg, sedation, dizziness). Hydrochlorothiazide is generally considered a second- or third-line agent for HTN during pregnancy due to theoretical concern for fetal growth restriction and oligohydramnios. Clonidine and prazosin have also been used during pregnancy, but use is generally reserved for patients being closely followed by maternal-fetal medicine or cardiology specialist. Atenolol is associated with fetal growth restriction and generally not utilized during pregnancy. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, renin inhibitors, and mineralocorticoid receptor antagonists are not recommended.[60]

The urgent need for blood pressure control in the setting of severe HTN is typically managed with intravenous labetalol, intravenous or intramuscular hydralazine, or immediate release oral nifedipine. Second-line treatment options include nicardipine or esmolol infusions. Once the patient's blood pressure is controlled, it is important to initiate oral maintenance therapy to maintain control.[61]

Intravenous magnesium sulfate is recommended in patients with severe HTN with preeclampsia to prevent the progression to eclampsia, and to treat eclamptic seizures. Although the duration of magnesium use varies, the usual duration is throughout active labor and continued for 12 to 24 hours postpartum. Benzodiazepines and phenytoin may be considered as treatment for eclampsia in patients with contraindications to magnesium (eg, myasthenia gravis, moderate-to-severe renal failure) or in settings where magnesium is unavailable.[60]

Low-dose aspirin (81 mg/day) prophylaxis is recommended for patients with one high-risk factor or two or more moderate-risk factors for preeclampsia (Table 99-3) to reduce the risk of preeclampsia.[64] Newer data suggests aspirin doses up to 150 mg may provide more protection; however, because this dose is not available in the United States, providers will often recommend 162 mg daily.[65] The exact mechanism of aspirin in the prevention of preeclampsia is not fully understood. Aspirin should be started between 12 weeks and 28 weeks gestation, ideally before 16 weeks, and continued daily until delivery.[66] In high-risk groups, adding low-dose aspirin in 50 pregnant individuals corresponds to preventing one case of preeclampsia.[39] Aspirin prophylaxis is also associated with a risk reduction for preterm birth, small for gestational age, intrauterine growth restriction, and perinatal mortality.[64]

Thyroid Disorders

⑥ Universal screening for thyroid disorders during pregnancy is not recommended.[67] During pregnancy, stimulation of the thyroid gland may occur because of hCG's structural similarity to thyroid-stimulating hormone (TSH; thyrotropin). This can occur in the first 12 weeks of gestation. In some individuals, gestational transient thyrotoxicosis (GTT) may result but treatment with antithyroid medication is usually not needed. Occurrence of GTT is often associated with HG and the nausea and vomiting can be treated as for patients without this pseudo-hyperthyroid state.[67]

Hypothyroidism is present in 2 to 10 per 1,000 pregnancies. Untreated hypothyroidism increases the risk of low birth weight, preeclampsia, premature birth, miscarriage, fetal death, and placental abruption; impaired neurological development in the fetus may also occur.[67] Causes of hypothyroidism include autoimmune diseases (eg, Hashimoto's thyroiditis), iodine deficiency (uncommon in the United States), and thyroid dysfunction following surgery or ablative therapy for previous hyperthyroidism.[67,68] If hypothyroidism is present, thyroid replacement should occur with levothyroxine. A reasonable levothyroxine starting dose is 1 to 2 mcg/kg/d or 0.1 mg/day. Individuals receiving thyroid replacement therapy before pregnancy are recommended to receive a 25% dose increase in levothyroxine once the pregnancy is confirmed. Laboratory follow-up of TSH should occur every 4 to 6 weeks during pregnancy to allow for dose titration according to TSH levels of the lower limit of the reference range up to 2.5 mU/L.[67]

Hyperthyroidism affects 0.2 to 0.7% of pregnancies and is associated with spontaneous abortion, fetal death, low birth weight, and medically indicated preterm delivery. Overall, 95% of hyperthyroidism in pregnancy is due to Graves' disease. Therapy includes the thioamides (eg, methimazole and propylthiouracil). Propylthiouracil is the preferred therapy during the first trimester because methimazole is associated with a higher risk for malformations. Although either thioamide can be used for the remainder of the pregnancy, many providers switch to methimazole because propylthiouracil has been associated with clinically significant hepatotoxicity. The risks of uncontrolled hyperthyroidism outweigh the risks of the thioamides. The goal of therapy is to attain free thyroxine concentrations near the upper limit of normal to allow for dose minimization and to limit fetal or neonatal hypothyroidism. Radioiodine is not recommended because of the risk of thyroid damage in the fetus. If adjunctive therapy is needed to treat symptomatic palpitations, propranolol is the preferred agent.[67]

Although not all pregnant individuals experience postpartum thyroiditis similarly, the typical presentation is characterized by transient hyperthyroidism during the first several months postpartum followed by a period of transient hypothyroidism between 4 and 8 months postpartum. Many cases spontaneously return to euthyroidism. The initial hyperthyroid state usually does not require treatment; however, β-blockers can provide symptomatic relief of adrenergic symptoms. Because postpartum thyroiditis is from a destructive inflammation process and not overproduction of thyroid hormone, antithyroid medications are ineffective. Up to one-third of individuals affected by postpartum thyroiditis develop permanent hypothyroidism.[67]

Thromboembolic Disorders

6 Thromboembolism is one of the most common causes of pregnancy related death in the United States. The risk of developing a venous thromboembolism (VTE) in pregnant or postpartum individuals is increased by fourfold to fivefold over nonpregnant individuals.[69] Low-molecular-weight heparin (LMWH) is recommended over unfractionated heparin and other anticoagulants for both treatment and prophylaxis.[69,70] Warfarin is reserved as a treatment option in patients with a mechanical valve.[69] Warfarin is not universally used because of the risk for multiple malformations, fetal bleeding, and fetal demise.[26,69] The direct oral anticoagulants (eg, dabigatran, rivaroxaban, apixaban, and edoxaban) are not recommended due to limited data.[25,26,69] If a patient is not a candidate for heparin products (eg, heparin induced thrombocytopenia, severe allergic reaction), fondaparinux should be considered.[69] Specific recommendations for using prophylaxis, intermediate, or dose-adjusted therapy can be found in the ACOG practice bulletin.[69] For acute thromboembolism, anticoagulation therapy should be continued throughout pregnancy and for at least 6 weeks after delivery; the minimum total duration should not be less than 3 months.[69]

Recurrent VTE is divided into three categories: low risk, intermediate risk, and high risk of recurrence. Antepartum monitoring is recommended for individuals with a single episode of VTE who have a low risk of recurrence such as those with one transient risk factor (ie, surgery, injury, lengthy travel, or immobility). For intermediate risk (ie, hormone-related, pregnancy-related, or unprovoked VTE) and high risk (ie, more than one unprovoked VTE or continuous risk factors), antepartum therapy with LMWH or heparin plus 6-week postpartum therapy with either LMWH or warfarin is recommended.[69] Specific recommendations for thrombophilias (eg, antiphospholipid antibodies, Factor V Leiden, prothrombin G20201A, protein C and S deficiencies) can be found in the ACOG Practice Bulletin addressing inherited thrombophilias in pregnancy.[70]

Anticoagulation management of individuals with mechanical heart valves during pregnancy is complex and requires a thorough discussion of the risks and benefits to allow for shared decision making. Management options include continuing warfarin throughout the pregnancy if the patient uses less than 5 mg/d, using dose-adjusted LMWH during the first trimester then warfarin during the second and third trimesters, or using dose-adjusted LMWH throughout the pregnancy. Although warfarin is the most effective therapy for patients with mechanical valves, it crosses the placenta and has fetal risks; however, it appears that doses less than 5 mg daily have less risk for malformations than doses greater than 5 mg daily.[25] Additionally, it has been associated with spontaneous abortion, fetal intracranial hemorrhage, neonatal death, and central nervous system defects.[25,26] Both LMWH and heparin therapies do not cross the placenta but may have a higher risk for thromboembolic events. When heparin products are utilized, dose adjustment should be made to achieve a peak anti-Xa at 4 to 6 hours post-dose of 0.8 to 1.2 U/mL (kU/L) or a prothrombin time (aPTT) at least twice the control value, respectively. Additionally, individuals with mechanical heart valves may also receive low-dose aspirin (75-100 mg/daily). Delivery planning is important to optimize therapy to decrease risks for both the patient and fetus, and patients are switched to unfractionated heparin prior to delivery. See the current American College of Cardiology/American Heart Association guidelines for specific recommendations. Individuals with bioprosthetic valves have a lower risk of thromboembolism than those with mechanical valves; however, management of anticoagulation during pregnancy is similar.[25]

Urinary Tract Infection

6 Urinary tract infections (UTIs) are common during pregnancy. Typically, UTIs are characterized as asymptomatic (eg, asymptomatic bacteriuria) or symptomatic (eg, lower [cystitis] or upper [pyelonephritis]). Similar to the nonpregnant population, *Escherichia coli* (*E. coli*) is the most common pathogen found in both asymptomatic bacteriuria and UTIs during pregnancy.[71] Asymptomatic bacteriuria occurs in 2% to 15% of all pregnancies, with most cases occurring during early pregnancy. When asymptomatic bacteriuria is left untreated, it progresses to a symptomatic UTI, including acute pyelonephritis, in 20% to 35% of pregnancies. In addition, it has been associated with increased risk for preterm birth and low birth weight; however, evidence is conflicting.[71]

Multiple organizations based in the United States recommend screening pregnant individuals for asymptomatic bacteriuria, although the timing is not universally agreed upon. The Infectious Diseases Society of American recommends pregnant persons be screened for asymptomatic bacteriuria at least once in early pregnancy (prior to 16 weeks gestation) with a urine culture.[72] Guidelines for rescreening patients with an initial negative culture are unclear and generally not recommended. Use of rapid screening tests, such as dipsticks, should be avoided because of the potential for false-negative results.[71]

Acute cystitis occurs in about 1% to 2% of pregnancies, whereas acute pyelonephritis occurs in up to 2%, with most cases occurring in the second or third trimesters.[72] Acute cystitis has not been associated with an increased risk for preterm delivery, low birth weight, or pyelonephritis, most likely because most pregnant individuals receive treatment for symptomatic UTIs. Pyelonephritis during pregnancy has been associated with preterm birth (primarily between 33 and 36 weeks gestation), anemia in the pregnant individual, sepsis and respiratory distress.[73] Treatment of asymptomatic bacteriuria and acute cystitis is necessary during pregnancy to help prevent progression to pyelonephritis and preterm delivery. The optimal therapy and treatment duration are not well defined. Local antibiograms should be used to direct empiric treatment while also considering medication exposure and safety to the fetus. A short-course therapy for asymptomatic bacteriuria is routinely accepted in practice, with a 3- to 7-day course commonly recommended.[71]

Beta-lactams (including penicillins and cephalosporins) have been widely used to treat asymptomatic bacteriuria and cystitis. Beta-lactams are not known teratogens; however, increasing resistance to ampicillin and amoxicillin limits their use as single agents.[74] Nitrofurantoin is not active against Proteus species and should not be used after week 37 in patients with glucose-6-phosphate dehydrogenase deficiency because of a theoretical risk for hemolytic anemia in the neonate. Sulfa-containing medications can contribute to the development of newborn kernicterus; use should be avoided during the last weeks of gestation. Trimethoprim is a folate antagonist and is relatively contraindicated during the first trimester because of associations with cardiovascular malformations.[74] Regionally, increased rates of resistance to trimethoprim-sulfa may limit its use. Single-dose fosfomycin may be considered, as it successfully treats bacteriuria and acute cystitis; however, use may be limited by lack of insurance formulary coverage.[75] Fluoroquinolones and tetracyclines are contraindicated because of potential associations with impaired cartilage development and deciduous teeth discoloration (if given after 5 months of gestation), respectively.[71]

Prophylactic or suppressive antibiotics may be considered in patients with recurrent cystitis.[75] Hospital admission for parenteral antibiotics is the standard of care for pregnant individuals with pyelonephritis. Intravenous antibiotics are utilized until the patient is afebrile for 24 to 48 hours and symptomatically improving; at that point antibiotic therapy can be converted to an oral regimen. Broad spectrum beta-lactam antibiotics, (eg, cefazolin, ceftriaxone, cefuroxime, ampicillin plus gentamicin) are preferred for the initial empiric treatment. Choice between specific agent should be guided by local antibiograms and patient tolerance. Nitrofurantoin and fosfomycin should be avoided because both fail to achieve therapeutic levels outside of the urine. In addition, fluroquinolones and aminoglycosides should be avoided when possible. Outpatient antibiotic therapy can be considered after initial inpatient observation in individuals who are afebrile and less than 24 weeks of gestation. The total duration of antibiotic therapy for acute pyelonephritis may vary by antibiotic reigimen, however in general is recommended for 7 to 14 days.[75]

Sexually Transmitted Infections

⑥ Sexually transmitted infections (STIs) in pregnant individuals range from infections that may be transmitted across the placenta and infect the infant prenatally (eg, syphilis) to organisms that may be transmitted during birth and cause neonatal infection (eg, Chlamydia trachomatis, Neisseria gonorrhoeae, or herpes simplex virus [HSV]) to infections that pose a threat for preterm labor (eg, bacterial vaginosis). Screening recommendations for STI during pregnancies as well as tests of cure and repeat testing that may be needed for various infections during pregnancy are provided in Table 99-4. Treatment for select STIs is summarized in Table 99-5.[76]

TABLE 99-4

STI Recommendations During Pregnancy

STI	When to Screen in Pregnancy	Wyhen to test of Cure after treatment	When to repeat Screening
Chlamydia	• 1st prenatal visit • less than 25 years old: all • greater than 25 years old: only if increased risk[a] • 3rd trimester: if at increased risk[a]	4 weeks after treatment	3 months after treatment
Gonorrhea	• 1st prenatal visit • less than 25 years old: all • greater than 25 years old: only if increased risk[a] • 3rd trimester: if at increased risk[a]		3 months after treatment
Hepatitis B[b]	All: 1st prenatal visit		
Hepatitis C	All (unless infection rate is less than 0.01%)		
HIV	All: 1st prenatal visit High risk[c]: 3rd trimester (before 36 weeks)		
Syphillis	All: 1st prenatal visit High risk[d]: 28 weeks and delivery	See guidelines for specific recommendations	

[a] Increased risk defined as not monogamous, multiple sexual partners, new sexual partner, or partner with an STI. Additionally, patients should have gonorrhea testing if they are diagnosed with other STIs during pregnancy.

[b] Individuals should be screened with the hepatitis B surface antigen. Individuals at high risk for hepatitis B should be vaccinated.

[c] High risk defined as injection substance users, STI diagnosed in pregnancy, not monogamous, new sexual partner during pregnancy, partner with HIV, receive healthcare in a facility with HIV incidence > 1 per 1,000 individuals per year, incarcerated, live in an area with high HIV rates, signs or symptoms of acute HIV (fever, lymphadenopathy, skin rash, myalgia, arthralgia, headache, oral ulcers, leukopenia, thrombocytopenia, or transaminase elevation).

[d] High risk defined as live in a community with high syphilis rate or at risk for syphilis infection during pregnancy (STI diagnosed in pregnancy, multiple partners, sex in conjunction with substance use or transactional sex, late or absent prenatal care, methamphetamine or heroin use, incarceration of the patient or her partner, unstable housing or homelessness) STI, sexually transmitted infection.

Data from Reference 76.

TABLE 99-5

Management of Sexually Transmitted Infections in Pregnancy

STI	Recommended Therapy	Alternative Therapy
Bacterial vaginosis	- Metronidazole 500 mg by mouth twice daily for 7 days - Metronidazole 0.75% gel 5 g intravaginally once daily for 5 days - Clindamycin 2% cream 5 g intravaginally at bedtime for 7 days	- Clindamycin 300 mg by mouth twice daily for 7 days - Clindamycin ovules 100 mg intravaginally at bedtime for 3 days
Chlamydia	- Azithromycin 1 g by mouth for 1 dose	Amoxicillin 500 mg by mouth three times a day for 7 days
Genital herpes	- Suppression (starting at 36 weeks) - Acyclovir 400 mg by mouth three times a day - Valacyclovir 500 mg by mouth twice daily	
Gonorrhea	Ceftriaxone 500 mg IM for 1 dose. If chlamydia has not been excluded, treat for chlamydia as well.	Consult with infectious disease specialists or STI clinical expert if patient has a cephalosporin allergy or other reasons to not use the preferred treatment.
Syphilis[a]		
Primary, secondary, early latent	Benzathine penicillin G 2.4 million units IM for 1 dose; a second dose can be given 1 week after initial dose to help reduce the risk for congenital syphilis	
Tertiary[b], late latent[c]	Benzathine penicillin G 2.4 million units IM for 3 doses at 1-week intervals	
Neurosyphilis, ocular syphilis, otosyphilis	Aqueous crystalline penicillin G 3-4 million units IV every 4 hours or 18-24 million units IV continuously for 10-14 days	- Procaine penicillin 2.4 million units IM daily for 10-14 days - PLUS - Probenecid 500 mg by mouth four times daily for 10-14 days
Trichomoniasis	Metronidazole 500 mg by mouth twice daily for 7 days	

[a] Pregnant individuals with history of penicillin allergy should undergo penicillin desensitization as no proven alternatives exist.

[b] With normal cerebrospinal fluid examination

[c] If a patient misses a dose (ie, greater than 9 days between doses), series needs to be restarted

CSF, cerebrospinal fluid; g, grams; IM, intramuscular; IV, intravenous; mg, milligrams; STI, sexually transmitted infection.

Data from Reference 76.

Syphilis

Syphilis is caused by Treponema pallidum and can cause many complications in pregnancy (eg, mucocutaneous lesions, altered mental status, visual and auditory abnormalities, gumma, cranial nerve palsies). Syphillis in a pregnant individual increases the risk for congenital syphilis, and all exposed neonates should be evaluated after birth. Ultrasound monitoring of the fetus to evaluate for congenital syphilis (eg, hepatomegaly, ascites, hydrops, fetal anemia, thickened placenta) should be performed if syphilis is diagnosed in the second half of pregnancy. If these signs are detected, a second dose of penicillin G may be administered for fetal treatment. Penicillin effectively prevents transmission to the fetus and treats the fetus, if already infected. Treatment during the second half of pregnancy may increase the risk for preterm labor and fetal distress because a Jarisch–Herxheimer reaction may occur; however, treatment should not be withheld or delayed.[76]

Chlamydia and Gonorrhea

Infections with both chlamydia and gonorrhea in pregnant individuals are capable of vertical transmission (passing of the infection from the pregnant individual to the neonate) through exposure of the infected cervix during delivery. Perinatal infections of *C. trachomatis* most commonly cause conjunctivitis that develops 5 to 12 days postpartum. A subacute, afebrile pneumonia with an onset at ages 1 to 3 months may occur.[76]

With *N. gonorrhoeae* infections, neonatal symptoms usually manifest within 2 to 5 days after delivery. Milder manifestations include rhinitis, vaginitis, urethritis, and scalp infections at sites where fetal monitoring electrodes were placed. More severe presentations include ophthalmia neonatorum and sepsis. Because untreated ocular infections can lead to perforation of the globe of the eye and blindness, the United States Preventative Services Task Force recommends all neonates receive ocular erythromycin ointment as prophylaxis within 24 hours after delivery.[76]

Bacterial Vaginosis and Trichomoniasis

Bacterial vaginosis and trichomoniasis infections characterized by vaginal discharge. Bacterial vaginosis is not a STI but is more common in sexually active individuals and may increase the risk for other STIs. Bacterial vaginosis results from the lack of normal vaginal flora (ie, *Lactobacillus* species) and replacement with anaerobic bacteria, mycoplasmas, and *Gardnerella vaginalis*. Untreated bacterial vaginosis increases the risk for premature rupture of membranes, preterm labor, preterm birth, intraamniotic infection, and postpartum endometritis.[76]

Trichomoniasis is caused by the protozoa, *Trichomonas vaginalis,* and infection is associated with an increased risk of premature rupture of the membranes, preterm delivery, and low birth weight. Treating the pregnant individual during pregnancy can help prevent neonatal respiratory and genital infections.[76]

Hepatitis Infections

Hepatitis infections may be identified during pregnancy with routine laboratory screening. Patients who have not been vaccinated for hepatitis A and/or B should be vaccinated during the pregnancy if they are at risk for the infections. Although several newer medications are available for treating hepatitis C infections, no recommendations are available now.[76] If a provider decides to treat during pregnancy, ribavirin-based regimens should be avoided.[26]

Genital Herpes

Neonatal herpes often occurs in infants born to individuals lacking histories of genital herpes. The risk of neonatal transmission is under 1% for those with a history of recurrent herpes at term or those who acquire herpes in the first half of pregnancy, but is 30% to 50% for individuals who initially acquire genital herpes near term. However, because recurrent herpes occurs more commonly than new acquisition during pregnancy, it remains the cause for most cases of neonatal transmission. Prevention strategies include counseling uninfected individuals to avoid intercourse during the third trimester with partners having known or suspected genital herpes infection. Individuals with no history of orolabial herpes should avoid receptive oral sex during the third trimester with partners who have orolabial herpes. Prevention of genital herpes transmission to pregnant individuals using antiviral agents has not been studied.[76]

All patients should be asked about symptoms of genital herpes at the time of delivery and should be examined for lesions. For those who have no symptoms (including prodromal symptoms) or lesions, proceed with vaginal childbirth; however, in those with evidence of an outbreak it is recommended that a cesarean section be performed to decrease the risk of neonatal transmission. Suppression therapy with either acyclovir or valacyclovir starting at 36 weeks decreases recurrence of genital herpes at term, which decreases the need for cesarean delivery.[76,77]

The Centers for Disease Control and Prevention (CDC) and ACOG recommend both medications, but both require more frequent administration during pregnancy due to increased renal elimination.[76,77] Although acyclovir may be less expensive, it needs to be administered three times a day whereas valacyclovir is administered twice daily during pregnancy. Both cost and adherence should be considered for patients.[77] For initial or recurrent episodes, most patients receive oral therapy; IV acyclovir is reserved for severe infections. In those seropositive for HSV but who have not experienced an outbreak, no data suggest a treatment benefit.[76,77]

Human Immunodeficiency Virus Infection

The rate of perinatal HIV transmission is 1% or less in the United States and Europe as a result of national recommendations for universal prenatal HIV counseling and testing, antiretroviral (ARV) therapy use, cesarean delivery if the HIV RNA is greater than 1000 copies/mL (1 x 10^6/L) near delivery, infant ARV therapy, and breastfeeding avoidance. The primary goal for HIV-infected individuals is to achieve sustained viral load suppression below the limits of detection before conception as well as throughout pregnancy and remainder of their life. ARV therapy should be started preconception for patients with known HIV, regardless of viral load or CD4 count, for the patient's health and to decrease the risk for perinatal and partner transmission. In patients newly diagnosed with HIV or who have not previously received ARV therapy, pharmacotherapy should be initiated as soon as pregnancy is determined since risk of perinatal transmission is lower with earlier viral suppression, and the regimen can be adjusted if needed after resistance results are available.[78] Recommendations regarding combination ARV therapy change frequently as new data becomes available, and providers should check the most up to date guidelines (https://aidsinfo.nih.gov).

For pregnant individuals with HIV RNA levels above 1,000 copies/mL (1 x 10^6/L) or unknown who are approaching delivery, a scheduled cesarean section at 38 weeks of gestation is recommended to reduce the risk of perinatal HIV transmission. Scheduled cesarean section is not recommended if HIV RNA levels are 1,000 copies/mL (1 x 10^6/L) or below because of the low rate of perinatal transmission. If the viral load is greater than 1,000 copies/mL (1 x 10^6/L) or not known, IV zidovudine should be initiated with a 1-hour loading dose (2 mg/kg) followed by a continuous infusion (1 mg/kg) for 2 hours with a minimum of 3 hours total. Intravenous zidovudine should still be administered in the presence of resistance to zidovudine. Consider administration of IV zidovudine to individuals with a viral load between 50 and 1,000 copies/mL (0.05 x 10^6 and 1 x 10^6/L) near delivery. Although there is inadequate information that zidovudine provides additional protection, there may be benefit as there is a slightly higher rate of transmission with a viral load in this range. Patients with a viral load below 50 copies/mL (0.05 x 10^6/L) near delivery do not require IV zidovudine, but they should continue their ARV therapy. Specific recommendations for different clinical scenarios during antepartum, intrapartum, and postpartum are provided in the clinical guidelines.[78]

Headache

⑥ Primary headaches (eg, tension and migraine) in pregnant and nonpregnant individuals are the most common types of headache. Hormonal fluctuations, particularly changes in estrogen, can be a trigger for headaches throughout pregnancy. Secondary headaches can also occur, indicating a more serious underlying condition, and include those caused by preeclampsia, stroke, postdural puncture, cerebral angiopathy, and cerebral venous thrombosis. Warning signs for a secondary headache include elevated blood pressure, altered mental status or confusion, fever, seizures, and abnormal findings on neurologic examination.[79]

Pregnant individuals with a history of migraine headaches have an increased risk of developing hypertension, pulmonary embolism, stroke, and myocardial infarction. The risk increases with age, and in overweight individuals. In early pregnancy, migraine frequency typically decreases, with improvement seen in roughly 50% of patients during the first trimester. By the third trimester, 87% of individuals have improved migraine symptoms and frequency. In 3% to 7% of cases, patients will experience new onset migraine headaches during pregnancy, typically developing during the first trimester.[79]

Relaxation therapy, cognitive-behavioral therapy, and biofeedback are all effective nonpharmacologic treatment methods that can be utilized during pregnancy. Sleep hygiene should be encouraged as a poor sleep pattern can increase headache frequency. In addition, maintaining adequate hydration, reducing caffeine intake, and exercise may all benefit as well.[79]

Pharmacologic treatment for migraines typically involves acetaminophen and antiemetics (eg, promethazine, prochlorperazine, and metoclopramide are most commonly used).[79] Opioids have been used but may contribute to migraine-associated nausea and routine use can increase migraine frequency and severity. Long-term use of opioids near the end of pregnancy can cause neonatal opioid withdrawal syndrome. For migraines that are not responsive to other treatments, triptans may be used. Of note, the package insert for sumatriptan indicates pregnancy as a contraindication for use; however, no human data have suggested teratogenicity for any medication in the triptan class.[79] Sumatriptan is the triptan of choice because medication transport across the placenta is small and it has a short elimination half-life of 2 hours. Migraine prophylaxis may be indicated for patients with frequent, disabling headaches to help decrease headache frequency and severity. A few dietary supplements have shown benefit for prophylaxis, and include daily riboflavin, or magnesium supplementation.[79] Ergotamine and dihydroergotamine are contraindicated because of effects on uterine tone.[26] Other typical migraine prophylactic therapy is often evaluated on an individual basis for medication safety and necessity.

Tension headaches are less studied; however, most patients report no change in the frequency or intensity of tension headaches, although remission is possible. Tension headaches are treated similarly, with acetaminophen being the treatment of choice for pain management. The NSAIDs are not recommended for use during pregnancy, particularly in late pregnancy (after 20 weeks gestation) or during labor and delivery, because they inhibit prostaglandin synthesis, which may cause harm including oligohydramnios, prolong labor, or premature closure or constriction of the ductus arteriosus.[26,79,80] Antiemetics may be added in patients experiencing nausea and vomiting. Opioids are rarely used.

Allergic Rhinitis and Asthma

⑥ Asthma and rhinitis are common chronic illnesses in pregnancy, and asthma affects approximately 4% to 8% of pregnancies.[81] During pregnancy, a third of patients have symptoms that worsen, a third will have symptoms improve, and a third will have symptoms remain unchanged.[82] Diagnosis, goals, and staging of asthma during pregnancy is the same as in nonpregnant individuals, although more frequent follow-up is necessary because of changes in disease severity. Bronchoprovocation should be avoided.[82] Health consequences of poorly controlled asthma include morbidity and mortality, preterm labor, preeclampsia, cesarean delivery, intrauterine growth restriction, premature birth, and low birth weight for infants; therefore, the treatment goal is to achieve and maintain control of asthma symptoms to prevent hypoxic episodes in both the pregnant patient and fetus.[81,82]

Risks of medication use to the fetus are lower than the risks of untreated asthma; therefore, use of medications to achieve and maintain control is warranted.[81,82] Routine pulmonary function evaluation, peak flow testing, and symptom monitoring are recommended during pregnancy because asthma severity can change during pregnancy.[81] Treatment recommendations are divided into multiple steps based on symptom control and follow a stepwise approach. Because inhaled corticosteroid therapy decreases the risk for exacerbations and discontinuation of these medications can significantly increase the risk for an exacerbation, the Global Initiative for Asthma (GINA) guidelines recommend continuing inhaled corticosteroids for individuals who are planning to become or are currently pregnant. Additionally, the GINA guidelines recommend that step down therapy should be a low priority until the patient is postpartum.[82]

Pre-existing or newly developed allergic rhinitis occurs during pregnancy and nasal congestion can be caused by pregnancy because of vascular engorgement in the nasal passages and hormonal effects on mucus secretion. Treatment strategies for allergic rhinitis during pregnancy are similar to those used in nonpregnant individuals and include avoidance of allergens, immunotherapy, and pharmacotherapy. Oral antihistamines and leukotriene receptor antagonists as well as intranasal antihistamines, decongestants (limit duration because of the risk for medication-induced rhinitis), cromones, and corticosteroids can be used. Oral corticosteroids may be considered when needed.[83] Immunotherapy is not contraindicated in pregnancy, however should not be initiated for the first time during pregnancy due to risk for anaphylaxis.[81]

Epilepsy

⑥ Seizure frequency does not change for most pregnant individuals with epilepsy. Of those who have been seizure free for at least 9 months prior to pregnancy, 84% to 92% will remain seizure free during pregnancy. Studies have demonstrated no change in seizure frequency in 54% to 80% of pregnant individuals with epilepsy, while decreased seizure frequency occurs in 3% to 24% and increased in approximately 14% to 32%.[84] Seizures may become more frequent because of changes in hormones, sleep deprivation, and medication adherence problems due to perceived teratogenic risk. Another potential cause is changes in free serum concentrations of antiseizure medications resulting from changes in absorption, increased volume of distribution in the pregnant individual, decreased protein binding from hypoalbuminemia, increased hepatic metabolism, and increased renal clearance.[24,85] A patient's clinical condition and serum concentrations, either total or free depending of the medication, should be the basis for dose adjustments, and some experts recommend checking levels preconception and monthly during the pregnancy.[24] The 2009 American Academy of Neurology guidelines recommends checking levels for lamotrigine, carbamazepine, phenytoin, levetiracetam, oxcarbazepine during pregnancy.[86] As more pregnancy evidence is available, additional agents may also benefit evaluating levels during pregnancy. New guidelines are anticipated to be released in 2022.

The risks of uncontrolled seizures to the fetus, particularly tonic-clonic seizures, are considered to be greater than those associated with antiseizure medications. Pregnant individuals with epilepsy are at an increased risk for spontaneous abortion, preeclampsia, pregnancy-induced hypertension, preterm labor and delivery, bleeding complications, death, and cesarean delivery compared to those without epilepsy.[21,24,84] Additionally, focal seizures with loss of consciousness are associated with uterine contractions and fetal heart rate changes whereas frequent tonic-clonic seizures have been associated with decreased neurodevelopment in the child.[24,85] However, major malformations are two to three times more likely to occur in children born to individuals taking antiseizure medications than to those who do not.[61] Teratogenic effects with some antiseizure medications are related to the dose, often with a threshold above which risks increase.[87] Major malformations with valproic acid are dose related and range from 4.7% to 13.8%.[24] Use of valproic acid should be avoided during pregnancy due to high risk of neural tube defects and facial clefts with first trimester exposure, and cognitive teratogenicity with exposure throughout pregnancy. Although many antiepileptic medications are associated with potential risks during pregnancy, including malformations, it is important to consider the benefits of preventing seizures to both the pregnant individual and the fetus. Because some organs form early in gestation, the ideal time to switch to a preferred therapy is prior to pregnancy.[21] Topiramate and zonisamide have been associated with lower birth weights and length.[88]

When possible, antiseizure medication monotherapy is recommended with medication regimen optimization occurring before conception. If gradual medication withdrawal is attempted because of epilepsy remission, it should be fully completed and evaluated before trying to conceive. Medication change to avoid use of valproic acid, phenytoin, carbamazepine, phenobarbital, and polytherapy is suggested during the first trimester; however, if either is used during pregnancy because of treatment failure with other medications, the lowest effective dose should be used.[21,24] All pregnant individuals taking antiseizure medications should receive folic acid supplementation starting before pregnancy and continuing through at least the first trimester. Many experts continue to recommend 4 mg daily dose, but this recommendation is not universal. Because evidence has not definitively shown the efficacy of high dose folic acid supplementation with antiseizure medications, the American Academy of Neurology recommends at least 0.4 mg daily.[86]

Mental Health Conditions

⑥ Psychiatric illness affects approximately 500,000 pregnancies each year.[89]

Depression occurs in approximately 17% of pregnant individuals. The risks associated with uncontrolled depression or bipolar disorder are similar, and include an increased incidence of low birth weight, decreased fetal growth, and postnatal complications including admission to neonatal intensive care units. In addition to the potential impact of depression during pregnancy on obstetric complications, untreated depression may cause the infant to cry more and be harder to console, and have long-term implications for normal infant development.[88] Symptoms of depression are often overlooked during pregnancy because they overlap with many symptoms of pregnancy (eg, irritable mood, weight loss or gain, appetite and sleep changes, fatigue/loss of energy). There are several survey tools that can be utilized during pregnancy and during the postpartum period to help distinguish depression symptoms from normal symptoms of pregnancy (eg, the Edinburgh Postnatal Depression Scale, Beck Depression Inventory, and Postpartum Depression Screening Scale). All patients should be screened for depression at least once in the peripartum period and at the initial postpartum visit.[90]

Anxiety disorders are also common during pregnancy, impacting an estimated 18% of adults 18 years and old. Anxiety during pregnancy is associated with spontaneous abortions, preterm delivery, and delivery complications including prolonged labor, precipitate labor, fetal distress, and forceps deliveries. Long-term anxiety during pregnancy has been linked to decreased developmental scores and inadaptability, and slowed mental development at 2 years of age. Obsessive-compulsive disorder (OCD) is a type of anxiety disorder. Although the incidence of OCD in pregnancy is unknown, pregnancy has been linked as a potential trigger for OCD symptom onset. In addition, OCD symptoms tend to worsen after delivery.[89]

Up to 70% of individuals with mental health conditions discontinue or refuse treatment because of concerns about teratogenicity.[91] Patients who stop taking antidepressants are more likely to relapse, which can also have implications for the well-being of the fetus. The risks and benefits of mental health medication use during pregnancy and the risks of untreated depression must be discussed with all patients in order to increase understanding. Because most mental health medications are used to treat more than one condition, the reader should refer to Chapters 80-90 for information about treatment of specific mental health diagnoses. In general, monotherapy is preferred over polytherapy even if higher doses are required.[89]

Selective serotonin reuptake inhibitors (SSRIs) are the most commonly used medication for depression and anxiety during pregnancy; however, serotonin-norepinephrine reuptake inhibitors (SNRIs) and atypical antidepressants are also utilized (see Chapter 88, “Depressive Disorders”). Conflicting studies about the risk of cardiac malformations with paroxetine are published in the literature.[26,92] One study found it was associated with doses greater than 25 mg a day.[26] Despite this association, SSRIs as a class are not considered major teratogens, as no consistent information supports an association with structural malformations,[92] and risks with SNRIs are less defined. Use of SSRIs and SNRIs in the latter part of pregnancy is associated with persistent pulmonary hypertension of the newborn and poor neonatal adaptation syndrome which encompasses transient neonatal complications of mild respiratory distress, tachycardia, weak or abnormal cry, poor muscle tone or color, irritability, tremor, jitteriness, lethargy, tachypnea, and rarely seizures. Symptoms are usually mild.[89,93,94] Second-generation antipsychotics are generally well tolerated and effective in managing symptoms of treatment-resistant depression. Second-generation antipsychotics can cause weight gain, gestational diabetes, and metabolic syndrome which have implications for poorer obstetric outcomes (see Chapter 87, “Schizophrenia”).[95] In addition, exposure to antipsychotic agents during pregnancy may increase preterm delivery and small for gestational age newborns, although evidence is inconsistent.[96,97] Some providers may also use buspirone for anxiety symptoms. Tricyclic antidepressants were commonly used in pregnancy before the introduction of SSRIs and are not considered major teratogens, although they have also been associated with a neonatal withdrawal syndrome when used late in pregnancy.[89,92]

In general, benzodiazepine use is not recommended during pregnancy. If patients are taking benzodiazepines during pregnancy, the benzodiazepine should not be abruptly discontinued due to risk for withdrawal. Benzodiazepine use in the third trimester can cause infant sedation and withdrawal symptoms (eg, restlessness, hypertonia, hyperreflexia, tremulousness, apnea, diarrhea, and vomiting) lasting up to 3 months postpartum. In addition, floppy baby syndrome is associated with benzodiazepine use before delivery and consists of hypothermia, lethargy, poor muscle tone, feeding difficulties, and poor respiratory effort.[89]

Mood stabilizers, such as lithium, lamotrigine, carbamazepine, and valproic acid, are often used to treat bipolar disorder.[89] The reader can find information related to the safety of antiseizure medications used for mood stabilization in Chapters 75, “Epilepsy” and 89, “Bipolar Disorder.” Abrupt discontinuation of lithium therapy during pregnancy is associated with an increased risk for relapse. Lithium use in early pregnancy has also been associated with cardiovascular anomalies, particularly Ebstein’s anomaly.[89] The risk of cardiac malformation was only found with doses higher than 900 mg daily.[98] In addition, when lithium is used during pregnancy providers need to be aware of potential changes in lithium levels due to pharmacokinetic changes, dehydration in the pregnant individual, and medication interactions. Because lithium use near term is associated with toxicities in the newborn, it is recommended that lithium is held starting 24 to 48 hours before or at the onset of labor. Once the patient is medically stable after delivery, therapy can be resumed.[26,99] Other reported neonatal adverse effects include floppy baby syndrome, nephrogenic diabetes insipidus, hypoglycemia, cardiac arrhythmias, thyroid dysfunction, polyhydramnios, and premature delivery. Lithium may cause lethargy, hypotonia, hypothermia, cyanosis, and changes in electrocardiogram in infants exposed through human milk. The decision to use lithium during pregnancy should be a shared decision making between the patient and provider, and be based on disease severity, history of illness, and timing of exposure. If breastfeeding, the infant’s lithium levels, thyroid function, hydration status, and complete blood count should be monitored.[89]

LABOR AND DELIVERY

Management of the pregnant individuals during the perinatal period often requires medication therapy for pain and for potential complications associated with labor and delivery.

Preterm Labor

⑦ Preterm birth occurs in approximately 12% of all live deliveries in the United States, and is the leading cause of infant mortality and hospitalization. Preterm labor is generally diagnosed when uterine contractions start before 37 weeks gestation in the presence of changes in cervical dilation and/or effacement, or when the initial presentation includes regular contractions and cervical dilation of at least 2 cm.[100] Risk factors for preterm delivery include previous preterm delivery, history of cervical surgery, short cervical length, infections, vaginal bleeding, UTIs, and periodontal disease. In addition, low prepregnancy weight, smoking, substance use disorders, and shorten interval between pregnancies have all been associated as increased risk factors for preterm delivery.[101]

Historically, nonpharmacologic recommendations have included bed rest, refraining from sexual intercourse and orgasm, and hydration; however, they do not decrease the risk and should not be routinely recommended. Pharmacologic interventions include tocolytic medications to stop uterine contractions, antibiotics to treat potential intrauterine infections, antenatal steroids to help with fetal lung maturation, and magnesium for fetal neuroprotection.[100]

Tocolytic Therapy

⑦ The purposes of tocolytic therapy are threefold: (a) postpone delivery long enough to allow for the maximum effect of antenatal corticosteroid and magnesium administration; (b) allow for transportation of the pregnant patient to a facility equipped to deal with high-risk deliveries; and (c) prolongation of pregnancy when there are underlying, self-limited conditions that can cause labor, such as pyelonephritis or abdominal surgery, that are unlikely to cause recurrent preterm labor. Tocolytics are generally not utilized before neonatal viability or beyond 34 weeks of gestation.[100]

Four classes of tocolytics are available in the United States: β-adrenergic receptor agonists, magnesium, calcium channel blockers, and NSAIDs. All four therapies prolong pregnancy between 48 hours to 1 week; however, this prolongation is not associated with a significant neonatal benefit. The β-adrenergic receptor agonist, terbutaline, has been used off-label for tocolytic therapy; however, it has been associated with a higher incidence of adverse effects in the pregnant individual, including hyperkalemia, arrhythmias, hyperglycemia, hypotension, and pulmonary edema. In addition, terbutaline has a boxed warning against oral dosing or prolonged parenteral use (beyond 48-72 hours) because of the risk of cardiotoxicity and death in the pregnant patient.[100]

Intravenous magnesium sulfate has been used for tocolysis; however, it is primarily utilized for fetal neuroprotection and reducing the incidence of cerebral palsy. Adverse effects associated with magnesium therapy in the pregnant individual are common and include a general feeling of warmth, flushing, diaphoresis, nausea, loss of deep tendon reflexes, and respiratory depression. If magnesium sulfate is used during preterm labor for fetal neuroprotection and the patient is still experiencing preterm labor, an additional agent should be added for short-term tocolysis.[100]

The calcium channel blocker, nifedipine, is also often used and associated with fewer adverse effects than magnesium or β-adrenergic receptor agonist therapy. Common adverse medication reactions include dizziness, flushing, and hypotension.[100]

The NSAIDs, such as indomethacin, have been used effectively for tocolysis. An increased rate of premature constriction of the ductus arteriosus has been noted in infants with indomethacin use after 32 weeks of gestation and with use exceeding 48 hours. In addition, indomethacin is the preferred tocolytic agent in patients receiving magnesium for neuroprotection prior to 32 weeks gestation, because other agents can cause hypotension when administered concurrently with magnesium.[100]

Other Medication Therapies for Preterm Labor Prevention

⑦ Intrauterine bacterial infections are a common cause of preterm labor before 32 weeks gestation. Infection and inflammation are thought to be associated with contractions; however, due to lack of evidence for improved outcomes, antibiotics are not routinely recommended for preterm labor. If a patient experiences prelabor rupture of membranes (PROM) before 34 weeks of gestation, prophylactic antibiotics should be initiated to prolong pregnancy, reduce infections in the patient and neonate, and reduce major morbidities including death, respiratory distress syndrome, early sepsis, severe intraventricular hemorrhage, and necrotizing enterocolitis. A 7-day course of broad-spectrum antibiotics should be used with the intent to prolong latency, which is the time from ruptured membranes to delivery. Multiple antibiotic regimens have shown benefit with a common regimen including IV ampicillin and erythromycin for 2 days followed by oral amoxicillin and erythromycin for 5 days. Amoxicillin-clavulanate is not recommended due to increased rates of necrotizing enterocolitis. In patients allergic to β-lactam antibiotics, another agent effective against Group B *Streptococcus* (GBS) may be considered to replace the β-lactam.[100]

Progesterone is also often administered in patients with a history of prior preterm birth. Progesterone use is based upon its effects to diminish cervical ripening (softening of the cervix necessary for cervical dilation before birth), reduce uterine wall contractility, and modulate inflammation. Evidence also supports progesterone supplementation in patients with no prior history of preterm birth who have a singleton pregnancy and a short cervix. Progesterone is not indicated for multiple gestation pregnancies. Progesterone supplementation is offered through either vaginal route or intramuscularly.[101]

Antenatal Corticosteroids

7 The ACOG recommends antenatal corticosteroids for fetal lung maturation to prevent respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and neonatal mortality in infants delivered prematurely.[100] Patients between 24 weeks and 34 weeks gestation who are at risk of preterm birth within the next 7 days, including those with ruptured membranes, are recommended to receive a single course of corticosteroids. When patients present between 23 and 24 weeks gestation, administration of corticosteroids may be considered. Due to the infant's small size and change of survival if delivered before 24 weeks gestation, the family's wishes regarding resuscitation must be carefully considered. In addition, a single course of steroids should be considered in patients presenting in the late preterm period between 34 and 37 weeks gestation who are at risk of delivery and have not previously received corticosteroids. The most common steroid regimens include betamethasone administered intramuscularly as two doses 24 hours apart and dexamethasone as four doses 12 hours apart for 48 hours. A rescue course is often administered to patients who have received a previous corticosteroid course more than 14 days prior who are at risk of delivering before 34 weeks gestation.[100]

Group B *Streptococcus* Infection

7 Between 10% and 30% of pregnant individuals are colonized with GBS, leading to an increased risk for pregnancy loss, premature delivery, and transmission of the bacteria to the infant during delivery. Approximately 50% of patients colonized with GBS will transmit the bacteria to their newborns. The consequences of neonatal infections include death, apnea, and need for blood pressure support and neonatal intensive care.[103]

Universal screening for GBS colonization is recommended between 36 and 38 weeks gestation. Intrapartum antibiotics are given if the patient has GBS colonization, or if they previously gave birth to an infant with invasive GBS disease, or GBS bacteriuria was identified at any time during the pregnancy. If a patient presents in labor and no screening information is available, antibiotics are given for fever greater than or equal to 100.4°F (38°C), amniotic membrane rupture at least 18 hours prior, gestation under 37 weeks, or known positive GBS colonization in previous pregnancy.[103]

Intravenous penicillin given every 4 hours until delivery is the recommended treatment regimen. Alternatively, ampicillin can be given IV, every 4 hours. For patients with a penicillin allergy but not at risk for anaphylaxis, cefazolin IV every 8 hours, is recommended. In patients at high risk for anaphylaxis, clindamycin IV every 8 hours is recommended. For penicillin-allergic patients, GBS cultures should be sent for sensitivities. If resistant to clindamycin or erythromycin, vancomycin IV every 8 hours until delivery is appropriate. A minimum of 4 hours of therapy with a beta-lactam antibiotic is required for adequate prophylaxis.[101]

Cervical Ripening and Labor Induction

7 Cervical ripening is the process of softening and thinning the cervix to facilitate labor. If a patient needs an induction and the cervix is not ready for labor, agents to induce cervical ripening may be utilized.

Nearly 26% of patients undergo labor induction, either elective or medically indicated.[102] The most common indications for induction are post-term pregnancies (beyond 42 weeks) and pregnancy-induced hypertension.[105] Other reasons for induction include fetal growth restriction or compromise, hypertension, premature rupture of membranes with no active onset of labor, and social factors. A number of nonpharmacologic methods are used for cervical ripening including membrane stripping, amniotomy, and nipple stimulation; however, available evidence is inconclusive on the efficacy of these methods.[105]

Prostaglandin E_2 analogs (eg, dinoprostone [Prepidil gel, Cervidil vaginal insert]) are commonly used for cervical ripening. Prepidil 500 mcg is administered intracervically and may be repeated after 6 hours to a maximum of three doses in 24 hours. After administration, the patient remains supine for 30 minutes. Cervidil contains 10 mg dinoprostone with a slower, more constant release of medication compared to the gel. The patient should remain in a recumbent position for 2 hours after placement and the insert should be removed when labor begins or after 12 hours. Fetal heart rate monitoring is recommended with both agents.[105]

Misoprostol, a prostaglandin E1 analog, is an effective and inexpensive medication for cervical ripening and labor induction. Intravaginal administration of misoprostol (oral tablets are split to obtain dose) given every 3 to 6 hours is at least as effective as other prostaglandin agents and results in a shorter time to delivery. Oral misoprostol has been used successfully and results in a quicker onset and shorter duration. Sublingual and buccal routes of misoprostol administration have less information regarding the efficacy compared to other routes. There is little benefit of using misoprostol for longer than 24 hours. The most common adverse effects are uterine hyperstimulation and meconium-stained amniotic fluid. Use of misoprostol is contraindicated in individuals with a previous uterine scar because of its association with uterine rupture, a catastrophic medical event.[105]

Oxytocin is the most commonly used agent for labor induction after cervical ripening. Patients may vary in response and sensitivity to oxytocin, but in theory administration should trigger a response similar to a spontaneous labor. Upon administration, a uterine response begins to occur after 3 to 5 minutes. Patients with a lower BMI, a greater cervical dilation at time of induction, more previous deliveries after 24 weeks gestation, and higher gestational age are more likely to have a successful response to labor induction from oxytocin. Refer to the ACOG practice bulletin for detailed administration information.[105]

Labor Analgesia

⑦ The first phase of labor occurs from onset of labor to complete cervical dilation, while the second phase of labor is the period of time between complete cervical dilation and delivery. During the first phase of labor, patients perceive visceral pain caused by uterine contractions.[104] Pain in the second phase of labor is somatic pain associated with perineal stretching.[106]

Nonpharmacologic Approaches to Analgesia

Massage, water immersion during the first stage of labor, and acupuncture, relaxation, and hypnotherapy have all been utilized for pain management during pregnancy.[106] In addition, the use of visualization and breathing techniques, yoga postures, massage, acupressure, and facilitated partner support lead to more vaginal deliveries, and have been shown to reduce epidural use and shorten the second stage of labor.[107]

Pharmacologic Approaches to Labor Pain Management

Labor causes considerable pain for many patients. The two main types of pharmacologic approaches in the United States are parenteral opioids and epidural analgesia. Use of nitrous oxide during labor is an alternative for pain management.

Parenteral opioids (eg, fentanyl, morphine, butorphanol) are commonly used to alleviate labor pain. Up to 42% of individuals receive parenteral medications, although there is no consensus that one agent is more effective or safe than another. Overall, though, they are less effective than epidural analgesia, have more adverse effects, and possibly less reliable pain response.[106]

Approximately 60% of pregnant individuals in the United States choose an epidural for pain relief during labor and report better pain relief than with other analgesic modalities.[108] With epidural analgesia, a catheter is introduced into the epidural space, and an opioid and/or an anesthetic (eg, fentanyl and/or bupivacaine) is administered. Combined spinal-epidural analgesia consists of injecting a single opioid bolus into the subarachnoid space to provide instant pain relief with additional use of a local anesthetic epidural. Compared with traditional epidurals, combined spinal-epidural anesthesia has a slightly shorter mean time to onset of effective analgesia.[106] Patient-controlled epidural analgesia results in a lower total dose of local anesthetics used over the course of labor compared with continuous epidural infusions.[106]

Adverse effects of regional anesthesia include hypotension, pruritus, and inability to void. Epidural analgesia is associated with prolongation of the second stages of labor, but it does not lead to higher numbers of instrumental deliveries, cesarean sections (for fetal distress), or fever when compared to intravenous opioid therapy.[108,109] A rare complication of epidural anesthesia is puncture of the subarachnoid space leading to a severe headache, which occurs in approximately 1% of patients. Other complications include hypotension, nausea, vomiting, itching, and urinary retention.[110] Low back pain has not been associated with the use of epidural analgesia.

Nitrous oxide, as a 50% mixture with oxygen, can be employed in patients desiring a non-medicated labor. It is less effective than epidural anesthesia but is quickly reversible and does not limit the patient's mobility.[106]

Postpartum Hemorrhage

7 Postpartum hemorrhage (PPH) in pregnant patients is defined as blood loss of more than 1,000 mL, regardless of vaginal or cesarean delivery, or blood loss with signs and symptoms of hypovolemia within 24 hours after delivery. There are various risk factors for PPH, some of which include prior PPH, incomplete placenta at delivery, a macrosomic fetus or multiple gestation, preeclampsia, operative vaginal delivery, chorioamnionitis, and prolonged or augmented labor.[111]

Administration of oxytocin should be initiated before placental delivery to institute active management of labor after all uncomplicated vaginal deliveries, as this practice results in reduced blood loss, fewer cases of PPH, and a shorter third stage of labor. Other uterotonic agents should be used if an inadequate response is attained with oxytocin alone. Methylergonovine, carboprost, and rectal, sublingual, or oral misoprostol can all be used as second-line agents. None has been shown to be more effective than another. Tranexamic acid, an antifibrinolytic agent, has been shown to reduce deaths from obstetric hemorrhage if given within 3 hours of delivery. A limited amount of evidence has shown a modest decrease in blood loss when tranexamic acid is given prophylactically. If uterotonic medication therapies fail to control the bleeding, a variety of different surgical techniques can be used.[111]

POSTPARTUM ISSUES

Medication Use During Lactation

8 A wide variety of benefits (eg, health, nutritional, immunologic, psychological, economic, developmental, and social) are imparted by breastfeeding, not only to the infants, but also to the family. The American Academy of Pediatrics recommends that infants be given human milk exclusively for 6 months and that this continue until at least 12 months of age while other foods are introduced, provided this is still desired by both the infant and parent.[113] Healthy People 2020 increased its target for breastfeeding to 81.9% for infants ever breastfed, 60.5% for infants at 6 months, and 34.1% for infants at 12 months.[112]

Adequate milk removal from the breast by nursing or pumping is necessary to maintain or increase milk production.[113] Milk supply is adequate when the baby is feeding 8 to 12 times per day, steady weight gain is by day 4/5 after delivery, and has 6 to 8 wet diapers per day; whereas signs of dehydration and low milk supply include jaundice, insufficient number of dry or soiled diapers, lethargy, inconsolability, stools are not bright yellow by day 5, and lack of steady weight gain by day 4.[114] Relactation is the process of increasing the milk supply for those whose milk has not "come in," who have inadequate milk production despite appropriate nursing frequency or pumping, or who have weaned or never breastfed after delivery. Nonpharmacological measures (massage, eating snacks and increasing hydration, looking at a picture of baby when pumping, listening to music, massaging downward toward nipple, applying warmth to the breast, pumping after feeding, decreased time between feeding/pumping, etc.) should be implemented first.[113–116] In fact, individuals producing breastmilk have an increased caloric need of 450 to 500 kcal/day (1.9 x 10^3 to 2.1 x 10^3 kJ/d).[112] Additionally, education, especially with a lactation specialist, may be helpful to review positioning, latching, and duration of feedings as pharmacologic and herbal agents efficacy is inconclusive. ACOG and the Academy of Breastfeeding Medicine do not recommend any specific galactogogues or use as a first-line agent due to the inconclusive evidence and potential for adverse events.[113,114] Although metoclopramide and domperidone have both used to increase milk production, both carry risk for the parent and infant. Metoclopramide may increase the risk for GI symptoms, extrapyramidal symptoms, and methemoglobinemia in the infant.[113,117] The FDA recommended against the use of domperidone during lactation because of cardiac arrhythmias, arrest, and sudden death. Because of the cardiac risks, it is not approved for any indication in the United States.[118] In circumstances where a patient has contraindications to breastfeeding, is unable to produce enough milk, or does not desire to breastfeed, formula is an acceptable option to consider for supplemental or full nutrition.

Most medications transfer into breast milk, but breastfeeding may be continued in most circumstances. Healthcare providers should encourage breastfeeding individuals who require medications to continue whenever possible. Passive diffusion is the primary mechanism for medication transfer into breast milk, but other medication-related factors influence medication transfer from parental circulation into breast milk, including (a) degree of protein binding in parental plasma, (b) molecular weight, (c) lipid solubility (and corresponding fat content of milk), (d) plasma concentration in the parent, (e) medication half-life, and (f) medication pH.[119] The degree of protein binding to parent plasma proteins is one of the most significant factors affecting medication transfer to breast milk; highly bound medications transfer in low amounts. Low-molecular-weight medications passively diffuse into breast milk, but larger molecules are not likely to transfer in large amounts. Higher lipid solubility of medications also increases the likelihood of transfer. Colostrum is secreted in the first couple of days after birth and has high quantities of immunoglobulins, parental lymphocytes, and parental macrophages. While greater amounts of medications are present in colostrum, the amount received by the nursing infant is minimal because of the limited volume of colostrum produced. A greater volume of mature milk is produced, but medication transfer into mature milk is lower because of tight cell-to-cell junctions. The higher the concentration of medication in the parent's serum, the higher the concentration in the breast milk. As the medication is metabolized and excreted by the parent, the parent's serum concentration drops, and the medication in the breast milk may redistribute back into the parent's bloodstream. The pH of plasma is 7.4, while the pH of breast milk ranges between 6.8 and 7. Weak bases are not ionized in the parental circulation and easily transfer to breast milk.[119] In the lower pH of breast milk, molecules become ionized and are less likely to diffuse back into parental circulation ("ion trapping"). Likewise, medications with longer half-lives are more likely to maintain higher levels in breast milk, resulting in greater exposure to the infant.

Infant-related factors may also influence the amount of medication ingested through breastfeeding as both the frequency of feedings and the amount of milk ingested are important considerations. Exclusively breastfed infants are more likely to ingest larger amounts of medications than older infants who receive other foods. Medication that are unstable in gastric acid (aminoglycosides, PPIs, and insulin) are less likely to be absorbed by infants.[119] Finally, infants may vary in their ability to metabolize and excrete ingested medication. Premature and full-term infants may not have full renal and liver function.

Strategies for reducing the risk to the infant include selection of medications that would be considered safe for use in the infant. Medications with shorter half-lives accumulate less, and those that are more protein bound do not cross into breast milk as well as those that are less protein bound. When choosing between different pharmacotherapies, medications with lower oral bioavailability and lower lipid solubility may be better choices to reduce infant exposure. If the parent is using a once-daily medication, administration before the infant's longest sleep period may be advised to increase the interval to the next feeding. For medications taken multiple times per day, administration immediately after breastfeeding provides the longest interval for back diffusion of medication from the breast milk to the parent's serum. During short-term medication therapy, the parent can pump and discard milk to preserve their milk-producing capability if the necessary medication is not considered compatible with breastfeeding.[120,121]

Information regarding medication use during breastfeeding is available from expert committees (eg, American Academy of Pediatrics Committee on Drugs) and evidence-based textbooks or databases (eg, LactMed [http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm]). All may be of assistance in determining safety and appropriate medications to use during breastfeeding.

Mastitis

8 Mastitis is inflammation of the breast that occurs in 3% to 20% of lactating individuals. It can be infectious or noninfectious and the most common cause is milk stasis. Signs and symptoms include breast tenderness, redness, warmth, flulike symptoms, chills, and fever (temperature 101.3°F [38.5°C] or greater). Risk factors for developing mastitis include breast engorgement, infrequent or short duration of feedings, poor attachment or uncoordinated suckling leading to inefficient milk removal, parental or infant illness, rapid weaning, pressure on the breast (eg, tight bra), parental stress and fatigue, plugged milk ducts, oversupply of milk, and cracked nipples.[122]

Penicillin-resistant *Staphylococcus aureus* is the most common bacterial cause of mastitis; *E. coli* and *Streptococcus* have also been implicated.[122] A 10- to 14-day course of antibiotics is usually given for treatment of mastitis; penicillinase-resistant penicillins (eg, dicloxacillin, oxacillin) and alternatively first-generation cephalosporins (eg, cephalexin) are frequently prescribed. Anti-inflammatory medications, such as ibuprofen, may provide some pain relief. Application of heat just prior to feeding may also be helpful along with direct massage of the affected area toward the nipple during feeding as tolerated. Additionally, cold compresses after feedings can be utilized to help decrease pain and edema. Affected individuals should be educated to continue breastfeeding from both breasts throughout treatment and to pump if breasts are not emptied completely with feedings. Feedings should start on the affected breast and occur more frequently.[122]

Postpartum Depression

8 Mood disorders in the postpartum period may include postpartum blues, postpartum depression, and postpartum psychosis.[122] Postpartum blues

("baby blues") is common, usually affecting 15% to 85% of new parents within the first 10 days of delivery, and generally does not require treatment. Symptoms include anxiety, anger, fatigue, insomnia, tearfulness, and sadness. Postpartum psychosis is more severe and can present as mania, psychotic depression, or schizophrenia but is rare, affecting less than 1% of new parents; hospitalization is usually indicated.[123]

Postpartum depression affects up to 13% of individuals, with almost 5% experiencing major depression. Symptoms may develop during pregnancy or up to 6 months after delivery, although the strict definition for major depressive disorder after delivery specifies symptom occurrence within 4 to 6 weeks.[123] Uncontrolled postpartum depression increases the risk for poor parental health, decreased quality of life, risky behaviors, relationship difficulties including bonding with and caring for the infant as well as impact infant physical health, growth, sleep, and development of motor, cognition, language, emotional, social, and behavior skills.[124] Psychotherapy, including interpersonal psychotherapy, cognitive behavioral therapy, and group/family therapy, has been shown to be effective for treatment of postpartum depression.[123]

Some suggest that the benefits of breastfeeding to the infant exceed the risks of antidepressant exposure in patients with postpartum depression. In cases where pharmacotherapy is warranted, selection of medication with low transfer to breast milk is desirable.[120] Sertraline, paroxetine, fluoxetine, and nortriptyline are the most studied in the postpartum period, however the FDA approved brexanolone for the treatment of postpartum depression (see Chapter 88, "Depressive Disorders"). Given the high unintended pregnancy rate in the United States, some experts would recommend against using paroxetine as this agent has been associated with potential risks in early pregnancy. Given that long-term effects of exposure to antidepressants are largely unknown, monitoring growth and neurodevelopment should be considered for children exposed to antidepressants present in breast milk.[120]

CONCLUSION

Pregnant individuals may experience pregnancy-influenced, acute, and chronic conditions during pregnancy, with some requiring pharmacotherapy. Medication exposure during pregnancy can elicit fear and anxiety since many believe that the risk of birth defects with exposure is high.

Very few medications carry an absolute contraindication for use during pregnancy and providers must weigh the risk of medication exposure with the risk of the untreated disease state using the available evidence and considering timing of exposure. Individuals using medications during pregnancy should be educated using this same approach. In some situations, opitimal parental health requires treatment with medications that have been associated with a higher risk of adverse effects to the fetus. The healthcare provider should provide realistic information about the types and likelihood of adverse effects to assist the patient in making the best possible decisions based on the patient's beliefs, concerns, and need for treatment.

Evidence-based resources, databases and reference books related to medication use in pregnancy and lactation, and primary and secondary literature provide healthcare practitioners with access to relevant and current medication information to manage medication therapy needs during pregnancy and lactation. Collaboration among healthcare providers who care for pregnant individuals is essential to seek, evaluate, and present the most up to date and accurate information to their patients.
